KEY POINTS

Psoriatic arthritis should be suspected in a patient with an asymmetric joint distribution pattern who may have additional clinical features, such as dactylitis, enthesitis, or inflammatory-type back pain, and who is negative for rheumatoid factor.

New classification criteria, the Classification of Psoriatic Arthritis (CASPAR) criteria, have been validated.

Psoriatic arthritis is a progressive disease, with 47% of patients developing erosions within 2 years of diagnosis. Polyarticular disease and an elevated erythrocyte sedimentation rate are markers of poor outcome.

An essential core set of domains and instruments is now agreed as being necessary for inclusion in clinical trials.

Studies of synovial tissue have highlighted an increase in vascularity and the presence of neutrophils as helping to distinguish spondyloarthropathy from rheumatoid arthritis. Change in synovial CD3⁺ T cell infiltration might correlate with clinical response to treatment.

Prominent enthesal involvement with bone marrow edema at enthesal insertions on magnetic resonance imaging has prompted the hypothesis that psoriatic arthritis may originate at the enthesis.

A role for CD8⁺ T cells and the innate immune response has been proposed.

Although there is a paucity of evidence for efficacy of disease-modifying antirheumatic drugs in psoriatic arthritis, tumor necrosis factor inhibitors have proved effective for skin and joint disease.

Psoriatic arthritis is a member of the spondyloarthropathy family and may be defined as an inflammatory arthropathy associated with psoriasis and usually negative for rheumatoid factor. Until the 1950s, an inflammatory arthritis occurring in the presence of psoriasis was thought to represent rheumatoid arthritis (RA) occurring coincidentally with psoriasis. Based primarily on clinical and radiologic grounds and using the rheumatoid factor, the distinction between RA and psoriatic arthritis became gradually accepted. Wright described the classic clinical features in 1959, and together with his colleague Moll, he published his classification criteria in 1973.^{1,2} These criteria have remained until recently the simplest and the most frequently used in clinical studies. The American Association of Rheumatism included psoriatic arthritis as a distinct clinical entity in the classification of rheumatic diseases for the first time in 1964.³

Psoriatic Arthritis

OLIVER FITZGERALD

EPIDEMIOLOGY

Epidemiologic studies have supported the concept that psoriatic arthritis is a unique disease entity separate from RA. The prevalence of inflammatory arthritis is increased among patients with psoriasis, ranging from 7% to 25% compared with a general population estimate of 2% to 3%. The prevalence of psoriasis among subjects with arthritis also is increased at 2.6% to 7% compared with a general population estimate of 0.1% to 2.8%.⁴

Psoriasis affects about 2% of the population. The prevalence varies, with 5% to 10% of Russians and Norwegians affected, and only 0% to 0.3% of West Africans or Native Americans affected.⁵ Onset of psoriasis may occur at any age, but it most frequently peaks in the 20s. Although no gender predilection has been reported, a genetic predisposition has been noted.

Among patients with psoriasis, 7% to 42% develop arthritis. This figure varies so widely in part because of a lack of widely accepted diagnostic criteria; it also varies according to which population is being studied. The exact prevalence and incidence of psoriatic arthritis are unknown. The reported prevalence of psoriatic arthritis ranged from 0.056% to 0.28% in a large population-based study in the United States.⁶ Cases were defined as patients who reported a "physician diagnosis" of psoriasis and psoriatic arthritis. Prevalence was calculated at 0.25% (95% confidence interval, 0.18% to 0.31%). Kay and colleagues⁷ did a prevalence study in northeast England to evaluate records from six general practices; 81 of 772 psoriasis subjects had an inflammatory arthritis with a prevalence of 0.28%. The reported incidence of psoriatic arthritis has varied from 3 to 23 cases per 100,000. Data from Rochester, New York, have shown an incidence rate of 6.59 per 100,000, whereas in Finland, 16 new cases of psoriatic arthritis were identified in a population of 87,000, yielding a mean incidence rate of 23 per 100,000.^{8,9} Using the Icelandic genealogy database, risk ratios (RRs) for developing psoriatic arthritis spanning five generations were estimated.¹⁰ Results confirmed a strong and complex genetic component with a significant risk ratio up to the fourth-degree relatives of psoriatic arthritis patients, as well as an important environmental contribution.

CLINICAL FEATURES

Plaque psoriasis or psoriasis vulgaris is the most common skin phenotype in patients with psoriatic arthritis. Other patterns of skin involvement may be seen (Figure 77-1). Although arthritis usually develops in a setting of an established diagnosis of psoriasis, some patients may be unaware that they have psoriasis, or psoriasis may develop after the onset of arthritis in approximately 15% of cases.¹¹ In a

clinical study, the incidence of development of arthritis in patients with psoriasis remained constant (74 per 1000 person-years), while the prevalence increased with time since diagnosis of psoriasis, reaching 20.5% after 30 years.¹² If a patient presents with the classic articular manifestations of psoriatic arthritis but does not volunteer psoriasis or the presence of a rash, it is incumbent on the physician to

examine the patient's skin carefully, including the scalp and nails, because psoriasis frequently lurks in such areas. Examples of nail dystrophic changes are shown in [Figure 77-2](#).

Although a more recent U.S. study suggests that the prevalence of psoriatic arthritis among psoriasis patients increases with psoriasis severity,⁶ in clinical practice, little relationship has been observed between severity of skin

involvement and severity of arthritis. In one prospective study, only 35% of patients reported that their skin and joint components flared at the same time.¹¹ Other systemic features of joint inflammation are common in patients with psoriatic arthritis, including stiffness after rest and fatigue. In one study of fatigue, a number of factors, including disease activity, physical disability, pain, and psychologic distress, contributed to fatigue, with comorbid fibromyalgia and hypertension further adding to the challenge.¹³ Compared with other core outcome measures, fatigue has been

found to be an independent outcome measure that is sensitive to change.¹⁴

Patients with psoriatic arthritis present with symptoms and signs of joint, enthesal, or spinal inflammation. The joints involved at presentation in 129 early psoriatic arthritis patients are shown in [Figure 77-3](#). In one of their seminal papers on psoriatic arthritis, Wright and Moll¹⁵ described five clinical patterns of psoriatic arthritis ([Figure 77-4](#)):

1. Asymmetric oligoarthritis
2. Symmetric polyarthritis

Figure 77-2 Nail dystrophic changes. **A**, Nail pitting; **B**, onycholysis; and **C**, severe destructive change with nail loss and pustule formation.

insertions. Other sites include the insertions of the quadriceps and patellar tendons, the iliac crest, the rotator cuff, and the epicondyles at the elbow. Patients have reported pain at these sites, with tenderness and sometimes swelling noted on examination. Enthesial involvement may be asymptomatic, and ultrasound is more sensitive than clinical palpation. Often spurs are detected on x-ray, although spurs are not always associated with symptoms.

With the obvious exception of psoriasis and nail dystrophic change, extra-articular disease is less common in psoriatic arthritis than in RA. Iritis or uveitis occurs in 7% to 18%, more bilateral than in ankylosing spondylitis, but is usually found in patients with spinal involvement.^{11,23} Numerous studies have suggested that psoriatic arthritis patients have a higher prevalence of inflammatory bowel disease, sometimes asymptomatic and detected only on biopsy specimen.^{24,25} Whether this inflammatory bowel disease is coincidental or is possibly related to medication effects remains to be clarified. Distal limb edema or lymphedema may occur more commonly in psoriatic arthritis; one case-control study found it in 21% of psoriatic arthritis patients compared with 4.9% of controls (see [Figure 77-4A](#)).²⁶ Finally, amyloid is rare but is described in psoriatic arthritis.

DIFFERENTIAL DIAGNOSIS

Certain articular features if present are useful in distinguishing psoriatic arthritis from RA, including dactylitis, DIP involvement, and inflammation at enthesial sites ([Table 77-1](#); see [Figure 77-4](#)). In addition, inflammatory-type back pain or sacroiliitis on plain x-ray or MRI should raise the suspicion of psoriatic arthritis because spinal involvement is uncommon in RA. The absence of rheumatoid nodules

Table 77-1 Clinical Features That Distinguish Psoriatic Arthritis from Rheumatoid Arthritis

	Psoriatic Arthritis	Rheumatoid Arthritis

Dactylitis	+	—
Nail dystrophy	+	—
Human immunodeficiency virus association	+	—

or other systemic features common to RA can be another useful differentiating feature.

Distinguishing psoriatic arthritis from other spondyloarthropathies is also important. Dactylitis may be a feature in reactive arthritis, where a palmoplantar pustular rash (keratoderma blennorrhagicum) may be clinically and histologically indistinguishable from pustular psoriasis (see [Figure 77-1G](#)). In relation to spinal involvement, sacroiliitis may be unilateral more frequently, and the spinal changes on plain radiography may be more asymmetric in psoriatic arthritis than with classic ankylosing spondylitis. Finally, crystal-associated arthropathies occasionally can confuse, especially with monoarticular disease, and are best distinguished by synovial fluid crystal analysis. Serum urate levels may be increased in patients with psoriatic arthritis, adding to the confusion. To aid dermatologists and general physicians in identifying those with psoriatic arthritis, a number of screening tools for arthritis in patients with psoriasis have been proposed and are the subject of a current head-to-head comparative study.

LABORATORY FEATURES

No diagnostic laboratory test for psoriatic arthritis is known. Although the absence of rheumatoid factor is considered an important distinguishing feature from RA, low levels of rheumatoid factor may be found in patients (5% to 16%) with typical psoriatic arthritis features. Until a more definitive diagnostic test becomes available, it is difficult to be categorical about diagnosis in these patients. Cyclic citrullinated peptide antibodies initially were thought to be specific to RA, but it is now recognized that cyclic citrullinated peptide antibodies are found in approximately 5% of psoriatic arthritis patients as well.²⁷ Acute phase markers, such as erythrocyte sedimentation rate, C-reactive protein, and serum amyloid A, may be elevated in psoriatic arthritis patients, but less commonly and to a lesser degree than in RA patients. These markers are elevated in particular in patients with polyarticular disease and act as a marker of poor prognosis.²⁸ Finally, as was mentioned previously, hyperuricemia may be found in association with metabolic abnormalities in psoriatic arthritis patients and may not reflect the extent of skin involvement.

RADIOGRAPHIC FEATURES

Although substantial advances have been made in the application, in particular, of musculoskeletal ultrasound (MSUS) and of MRI in patients with arthritis, including psoriatic arthritis, plain radiographic imaging remains the “gold standard” for assessing bony changes in peripheral joints in psoriatic arthritis.

Plain Radiography

Sixty-seven percent of patients with established psoriatic arthritis have radiographic abnormalities,¹¹ and 47% of patients with recent-onset psoriatic arthritis will have developed erosions within 2 years of disease onset.¹⁶ Distinctive radiographic features reflect in some cases the clinical phenotype ([Figure 77-5](#)). These features include asymmetric joint involvement; involvement of the interphalangeal

joints of the fingers and toes, with features of bony erosion and resorption sometimes seen together and resulting in the classic “pencil-in-cup” deformity; joint space narrowing or involvement of enthesal sites, often with bony spurs or periostitis developing; and spinal involvement, frequently less severe and asymmetric than in classic ankylosing spondylitis.

Radiographic progression in psoriatic arthritis is slow in early stages of the disorder, with the mean modified Sharp (to include DIP joints in the hands) erosion score at presentation increasing from 1.2 to 3 at 2 years.¹⁶ Larson and Sharp scoring systems have been used in psoriatic arthritis, but neither the Larson nor the Sharp score has been developed specifically for psoriatic arthritis or has been extensively validated.

Musculoskeletal Ultrasound

Many MSUS applications are useful in psoriatic arthritis; these applications are likely to develop further as the technology (in particular, power Doppler) that can be used to allow identification of blood flow is further advanced ([Figure 77-6](#)). Already it has been shown that MSUS is more sensitive than clinical examination in detecting knee synovitis in patients with various arthritides, including psoriatic arthritis.²⁹ One study has suggested further that this increased sensitivity may result in reclassification of some patients as polyarticular when they were previously diagnosed as oligoarticular on clinical grounds.³⁰ This reclassification may result in significant changes in prognosis and therapy. Finally, MSUS has been used in objective monitoring of the response of synovitis to therapy.³¹

MSUS features at the enthesis include enthesal thickening, hypoechoic change, increased vascularity as shown on power Doppler, tenosynovitis, and bony erosions or enthesophyte formation.^{32,33} MSUS has been shown to be more sensitive than clinical examination in detecting lower limb enthesopathy.^{33,34} MSUS has been used in studies of dactylitic digits. Together with MRI, MSUS has shown dactylitis to be due to a combination of synovial and tenosynovial inflammation.^{21,22} Finally, MSUS guidance for small joint or enthesal aspiration or injection may have particular application in patients with psoriatic arthritis.

Magnetic Resonance Imaging

MRI studies have been particularly useful in offering new insights into disease pathogenesis in psoriatic arthritis. Based on the prominent enthesal-related bone marrow edema seen on MRI, McGonagle and colleagues³⁵ have proposed that psoriatic arthritis, in contrast to RA, is an enthesal-based disease. MRI can be used to study all aspects of joint involvement, including the enthesis, but use of MRI as a routine clinical tool in psoriatic arthritis has not been clarified. Application of MRI to the spine or sacroiliac joints in psoriatic arthritis may prove especially helpful, as has been shown in ankylosing spondylitis, but studies in psoriatic arthritis patients are awaited. Preliminary studies have suggested that MRI can be useful as an outcome measure in the detection of synovitis or of vascularity in patients with psoriatic arthritis undergoing biologic therapies ([Figure 77-7](#)). More detailed studies are required. A new MRI

(Courtesy Dr. Robin Gibney.)

scoring system has been proposed to measure articular inflammation and damage in patients with psoriatic arthritis (PsAMRIS).³⁶

Other Imaging Modalities

The use of other imaging modalities, such as computed tomography (CT) or scintigraphy, has largely been superseded by MRI. CT is now reserved mainly for patients for whom MRI is contraindicated, or for whom MRI is unavailable. Positron emission tomography has been found to be comparable with MSUS and MRI in RA knees; this work needs to be extended to psoriatic arthritis. In a study using high-resolution CT imaging, structural bone changes were compared between RA and psoriatic arthritis. Smaller Ω -shaped and tubule-shaped erosions, as well as large sometimes corona-shaped osteophytes, are typical of psoriatic arthritis.³⁷

DIAGNOSIS

A diagnostic test for psoriatic arthritis is currently unavailable. Nevertheless, in its simplest form, psoriatic arthritis can be considered as an arthritis occurring in the presence of psoriasis, but in the absence of rheumatoid factor. Most psoriatic arthritis patients meet this simple definition. The arthritis can be predominantly spinal, it may involve only

enthesal sites, psoriasis may present after arthritis in 15% of cases, and low-titer positive rheumatoid factor may be found. Recognizing these difficulties, the CASPAR group published new classification criteria based on an analysis of 588 psoriatic arthritis cases and 536 controls (Table 77-2).³⁸ These criteria have yet to be validated in other large patient cohorts, and they should not be used in individual patient diagnosis. In the setting of clinical research, the CASPAR criteria have a specificity of 0.987 and a sensitivity of 0.914. For the individual patient, an algorithm for diagnosis is suggested in Figure 77-8.

CLINICAL COURSE AND OUTCOME

Five early psoriatic arthritis cohorts have been studied.^{16,39-42} The mean disease duration in these cohorts was 6 to 12 months, the median age at onset of psoriasis was 27 to 31 years, and the median age at onset of arthritis was 38 to 52 years. Overall, little relationship was noted between skin disease severity and onset of psoriatic arthritis; the small joints of hands and feet were most commonly involved; the DIP joints were involved in one-third of patients, usually in association with nail disease, which was present in two-thirds; dactylitis and enthesitis were present in one-third; and spinal involvement only was found in 2% to 4%, but was present in 20% overall. At follow-up, disease had continued to progress in most patients, with 47% developing

Table 77-2 CASPAR Classification Criteria for Psoriatic Arthritis

Inflammatory articular disease (joint, spine, or enthesal) with ≥ 3 points from the following:	
1. Evidence of psoriasis (one of a, b, or c)	
a. Current psoriasis*: psoriatic skin or scalp disease present today as judged by a rheumatologist or dermatologist	
b. Personal history of psoriasis: history of psoriasis that may be obtained from patient, family physician, dermatologist, rheumatologist, or other qualified health care provider	
c. Family history of psoriasis: history of psoriasis in a first-degree or second-degree relative according to patient report	
2. Psoriatic nail dystrophy: typical psoriatic nail dystrophy, including onycholysis, pitting, and hyperkeratosis observed on current physical examination	
3. Negative test for rheumatoid factor: by any method except latex, but preferably by ELISA or nephelometry, according to the local laboratory reference range	
4. Dactylitis (one of a or b)	
a. Current swelling of an entire digit	
b. History: history of dactylitis recorded by a rheumatologist	
5. Radiologic evidence of juxta-articular new bone formation: ill-defined ossification near joint margins (but excluding osteophyte formation) on plain x-rays of hand or foot	

*Current psoriasis scores 2, whereas all other items score 1. Specificity 0.987, sensitivity 0.914.

CASPAR, Classification of Psoriatic Arthritis; ELISA, enzyme-linked immunosorbent assay.

erosive disease within 2 years.¹⁶ Markers for progression included polyarticular disease and an elevated erythrocyte sedimentation rate. Long-term follow-up studies have shown significant morbidity and increased mortality in psoriatic arthritis: 17% of patients have five or more deformed joints, 40% to 57% have a deforming arthritis, 20% to 40% have spinal involvement, 11% to 19% are disabled, and mortality is increased compared with the general population.^{11,43,44} In one study, carotid intimal medial thickness was increased in psoriatic arthritis patients compared with

controls (but was significantly reduced compared with an RA cohort of similar disease duration [unpublished observations]).

COMORBIDITIES IN PSORIATIC ARTHRITIS

Similar to the recent emphasis on the importance of comorbidities in psoriasis,⁴⁵ a number of studies have highlighted cardiovascular risk factors and the metabolic syndrome in psoriatic arthritis. In one study of 109 psoriatic arthritis patients compared with 699 RA and 122 ankylosing spondylitis controls, the adjusted odds ratio for the metabolic syndrome was 2.44 (1.48 to 4.01; $P < .001$) with adjusted odds ratios significantly increased for central obesity, impaired fasting glucose, and low high-density lipoprotein (HDL) cholesterol.⁴⁶ The European League Against Rheumatism (EULAR) has published evidence-based guidelines for cardiovascular risk management in patients with inflammatory arthritis.⁴⁷

OUTCOME DOMAINS AND INSTRUMENTS

Measuring response to treatment of psoriatic arthritis in clinical trials has been the subject of much interest for members of the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) and Outcome Measures in Rheumatoid Arthritis Clinical Trials (OMERACT). Many of the data that have been used to date in clinical trials have been adapted from RA and have not been validated. Controversial issues have included the number of joints to count, the usefulness of the acute phase response in psoriatic arthritis, and how important is it to include a measure of function or quality of life. An essential core set of domains that must be included in clinical trials has now been agreed on, with other domains necessary but not mandatory, and yet others requiring considerably more research (Figure 77-9). Instruments for many of these domains have yet to be developed and validated, and some instruments, such as the Psoriasis Assessment Severity Index (PASI), have acknowledged limitations. Table 77-3 lists the currently available instruments for the core domains. Instruments for dactylitis and enthesitis have been proposed and validated.^{48,49}

In the setting of clinical trials, numerous composite scores (e.g., American College of Rheumatology [ACR]20, ACR50, ACR70; EULAR Disease Activity Score [DAS] response criteria) have been used in psoriatic arthritis, most again adapted from RA and not extensively validated in psoriatic arthritis. One scoring system was developed for psoriatic arthritis—the PsARC; although it has been used in numerous studies, it too has not been extensively validated and is considered perhaps insufficiently responsive and discriminant.⁵⁰ Much work is required to develop a validated and responsive composite instrument for psoriatic arthritis. More recently, minimal disease activity criteria were developed and validated,⁵¹ and two disease activity indices have been proposed. The Disease Activity index for Psoriatic Arthritis (DAPSA) appears to work well for

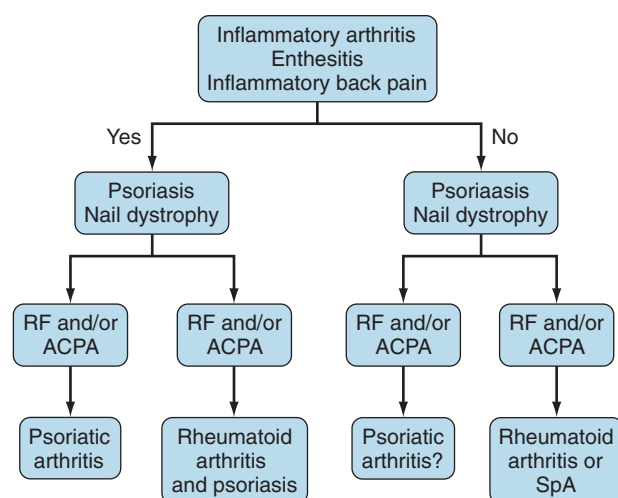

Figure 77-8 Algorithm to be used in the diagnosis of individual patients presenting with possible psoriatic arthritis. Some patients may present with typical articular manifestations of psoriatic arthritis, but in the absence of skin or nail disease. They can be diagnosed as having definite psoriatic arthritis only when psoriasis subsequently develops. ACPA, anticitrullinated protein antibody; RF, rheumatoid factor; SpA, spondyloarthritis.

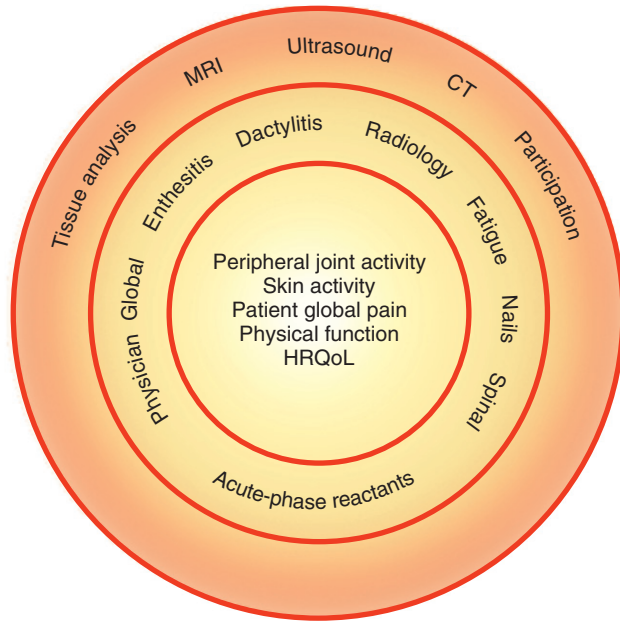

Figure 77-9 Outcome domains in psoriatic arthritis. The central core domains are considered essential for inclusion in clinical trials. The middle circle contains domains that are considered important but not essential. The outer circle contains domains that all require further research and validation. CT, computed tomography; HRQoL, health-related quality of life; MRI, magnetic resonance imaging.

joint-related disease and is easy to apply.⁵² The Composite Psoriatic Disease Activity Index (CPDAI) better reflects all of the domains potentially involved in psoriatic arthritis⁵³; thus unlike the DAPSA, this instrument could distinguish treatment responses between two doses of etanercept in the PRESTA trial dataset (FitzGerald, personal communication). Finally, Gladman and colleagues used data from placebo-controlled trials.⁵⁴

Table 77-3 Core Set Instruments Proposed for Use in Clinical Trials

Domain	Instrument
Peripheral joint inflammation	Tender/swollen joint count 68/66
Patient global assessment	Instrument under study proposed*
Skin assessment	Psoriasis Assessment Severity Index (if body surface area $\geq 3\%$) Lesion score (erythema, induration, scale) Body surface area
Pain	Visual analogue scale or numeric rating scale
Physical function	HAQ/SF-36 physical function composite
Health-related quality of life	Generic Disease specific (e.g., DLQI, PsAQoL)

PATHOGENESIS

Many studies have explored key components of disease pathogenesis, including the contribution of genetic factors, the role of infection or trauma, studies of animal models or involved sites of disease, and the importance of components of the immune system such as cytokines.

Genetic Factors

Familial clustering of psoriasis and psoriatic arthritis is well described. Twin studies in psoriasis have shown a high rate of concordance in monozygotic twins.⁵⁵ The genetic basis for this clustering has been the subject of extensive investigations in psoriasis, but has been much less well studied in psoriatic arthritis. Studies of psoriatic arthritis have often included patients as a subset of larger psoriasis cohorts, and the diversity of clinical phenotypes has not often been recognized.

A strong association between psoriasis and the human leukocyte (HLA)-C region of the major histocompatibility complex (MHC) has long been recognized. Whether this was HLA-Cw6 itself, found in approximately 60% of psoriasis cohorts, or a region telomeric to this has been the subject of much controversy. Elder⁵⁶ definitively showed that the HLA susceptibility region for psoriasis is HLA-Cw6, which is often in linkage disequilibrium with other HLA-B alleles such as HLA-B57, HLA-B37, and HLA-B13. The presence of HLA-Cw6 is associated with an earlier age of onset of psoriasis (type 1 disease, <40 years old) and with more extensive and severe disease. In individuals with psoriatic arthritis, the association with HLA-Cw6 is slightly weaker, whereas additional associations have been found with HLA-B27, chiefly in patients with predominant spinal disease, and with HLA-B38 and HLA-B39.⁵⁷

These findings have been interpreted to suggest that the MHC association with psoriasis lies close to the HLA-C region, whereas the association with the articular manifestations more likely lies in or close to the HLA-B region. A study of a large cohort of psoriatic arthritis patients in the United Kingdom has found HLA-Cw6 to be in linkage disequilibrium with HLA-DRB1*07, and that possession of both alleles was associated with fewer involved or damaged joints (Pauline Ho, personal communication, 2007).⁵⁸

Other genes within the MHC region have been explored in psoriasis and psoriatic arthritis. Tumor necrosis factor (TNF) promoter polymorphisms or a gene in linkage disequilibrium with TNF may predispose the patient to or increase susceptibility to psoriasis and to psoriatic arthritis. One study has found further an association between the TNF-308 A allele and disease progression in early psoriatic arthritis.⁵⁹ Whole-genome scans in psoriasis have identified additional non-MHC susceptibility regions, known as the PSORS regions on chromosomes 4, 6, and 17. To date, no candidate genes have been identified.

Increasing evidence suggests that an additional or distinct genetic contribution is responsible for the development of psoriatic arthritis. Investigators have pointed to an MHC class I chain-related A (MICA)-A9 polymorphism, which confers additional relative risk, in particular for polyarticular disease, in psoriasis patients who carry Cw*0602.⁶⁰ MICA-A9 polymorphism was found in linkage

disequilibrium with HLA-B alleles (B*5701, B*3801). These results suggest that the *MICA* gene or other nearby genes may be involved in the development of psoriatic arthritis. Additionally, a genome scan identified a paternally influenced locus on chromosome 16—a region not known to be implicated in psoriasis susceptibility.⁶¹

Finally, two genome-wide association studies in psoriatic arthritis have been reported.^{62,63} These studies have confirmed associations with HLA-C and interleukin (IL)-12B, and they have identified a new susceptibility region TRAF3IP2 on chromosome 6p, which encodes a protein involved in IL-17 signaling, and which interacts with members of the Rel/ nuclear factor κ B (NF κ B) transcription factor family.

Environmental Factors

The role of environmental factors in triggering skin or joint disease in patients with psoriasis or psoriatic arthritis has been supported largely by clinical observations, although the mechanism is poorly understood. It has long been recognized that there is a strong association between guttate psoriasis and preceding streptococcal infections in children.⁶⁴ That this association might be related to a streptococcal superantigen has been proposed. Some authors have found bacterial antigens in synovial tissue samples from psoriatic arthritis patients, but this may be no different from those in noninflammatory control subjects.⁶⁵

The Koebner phenomenon (see Figure 77-1H) has been reported to occur in 52% of patients with psoriasis. The Koebner phenomenon is the development of psoriasis along the site of skin trauma. It has been proposed that trauma may play a role in triggering episodes of joint inflammation, and the term *deep Koebner phenomenon* has been coined. Although the role of trauma has not been proved, in one study, 24.6% of patients reported a traumatic event before the onset of arthritis.⁶⁶

Finally, a link between stress and exacerbation of psoriasis has been proposed, supported largely by clinical observational studies. A similar association may exist in psoriatic arthritis, but this has not been systematically examined.

Animal Models

Although spondyloarthropathy has been detected in a variety of primates, rodent models have proved helpful in deciphering pathogenic pathways. In rodents transgenic for HLA-B27 class I molecules, skin, nail, and joint features have been described that mimic some of the features of the human phenotype.⁶⁷ When HLA-B27 transgenic rats were raised in a germ-free environment, they seemed to be protected from joint disease. Mice genetically lacking MHC class II have developed skin and joint disease, but confined to the distal phalanges with skin and nail disease also on the affected digits.⁶⁸ Involvement of the distal phalanges and nails was reported in aging male DBA/1 mice from different litters that were caged together from 12 weeks.⁶⁹ In these animals, dactylitis, periostitis, and ankylosing enthesitis were observed.

Finally, JunB protein was shown to be expressed in normal and in clinically uninvolved psoriatic skin, but

expression was considerably reduced in involved psoriatic lesions.⁷⁰ Epidermal deletion of JunB and c-Jun in a mouse model resulted in skin and joint disease with 100% penetrance and a clinical and histologic phenotype highly consistent with human psoriasis and psoriatic arthritis. In further experiments, the same authors showed that the joint disease, but not the skin disease, required T and B cells and intact TNF receptor 1 signaling.

Immunopathology

The key pathologic events in psoriatic arthritis occur in the skin, synovium, enthesal sites, and cartilage and bone. Pathobiologic features in the skin and synovium have been well described, but only a few studies have focused on the enthesis. In relation to cartilage and bone, studies have shown the presence of osteoclasts at the cartilage-pannus junction and high numbers of circulating osteoclast precursors in the circulation of psoriatic arthritis patients. Detailed studies similar to those done on RA on the synovial-cartilage-bone interface possibly could yield valuable information regarding joint destruction in psoriatic arthritis.

Psoriasis Skin

Involved psoriasis skin is characterized by epidermal hyperplasia, mononuclear leukocytes in the papillary dermis, neutrophils in the stratum corneum, and an increase in various subsets of dendritic cells.⁷¹ CD8⁺ T cells are the predominant T cell subset chiefly found in the epidermis, whereas dermal T cells contain a mixture of CD4⁺ and CD8⁺. Most T cells in skin lesions express addressin, a cutaneous lymphocyte antigen, in contrast to circulating T cells and T cells found in the inflamed synovium in psoriatic arthritis.⁷² Finally, vascular changes are prominent in psoriasis with impressive growth and dilation of superficial blood vessels.

Psoriatic Synovium

Many early studies of synovial pathology in psoriatic arthritis highlighted the presence of prominent and striking vascular changes. In the first study that compared psoriatic arthritis and RA synovial tissue, quantitative immunopathologic analysis confirmed these prominent vascular changes and found that vessel number was significantly increased in psoriatic arthritis.⁷³ Lining layer hyperplasia was less marked in psoriatic arthritis, and fewer macrophages were seen trafficking into the synovium and out to the lining layer. The numbers of T lymphocytes and their subsets and the number of B cells were similar to the frequency found in RA. Although neutrophil infiltration was not assessed, this study examined adhesion molecule expression further in the two patient subgroups and found E-selectin expression to be considerably reduced in psoriatic arthritis. Many of these observations have been confirmed by other authors.

In a study by Kruithof and co-workers,⁷⁴ the synovial immunopathologic features in patients with spondyloarthropathy, including psoriatic arthritis, were compared with the features seen in RA.⁷⁴ Using a semi-quantitative scoring system, the authors identified many features characteristic of the spondyloarthropathy group as a whole and in the

psoriatic arthritis subgroup alone. Increased vascularity, higher neutrophil numbers (also seen in involved psoriasis skin), and a higher number of infiltrating CD163⁺ macrophages, a marker of mature tissue macrophages, reliably distinguished spondyloarthropathy from RA. No significant differences were seen between oligoarticular versus polyarticular psoriatic arthritis.

The important role of the vasculature in psoriatic arthritis pathogenesis is perhaps most elegantly shown by the large numbers of tortuous and dilated blood vessels observed through an arthroscopic view of psoriatic joints.⁷⁵ An interaction of key growth factors is thought to regulate closely the new vessel formation or angiogenic process. Growth factors, including TNF, transforming growth factor (TGF)- β , platelet-derived growth factor (PDGF), angiopoietins (ANG-1, ANG-2), and vascular endothelial growth factor (VEGF), have been described in skin and synovial tissue.^{76,77} Because this expression is found at an early stage of inflammation, it may represent a primary event in psoriatic arthritis as opposed to a reaction or response to hypoxia. One possibility is that there is a genetic predisposition to endothelial activation, which results in new vessel formation and increased cellular trafficking.

Of interest, two studies have identified a change in synovial CD3⁺ T cell infiltration as correlating with clinical response in patients commencing biologic therapies⁷⁸ (Pontifex, personal communication). Changes in CD3 infiltration also correlated with changes in MRI assessment of synovitis (Pontifex). Changes in CD3 infiltration may well prove to be a useful tissue biomarker of treatment response.

Entheseal Sites

Laloux and associates⁷⁹ described the immunopathologic features of the enthesitis in patients undergoing joint replacement surgery with spondyloarthropathy, including psoriatic arthritis, and compared them with RA. The number of patients was small in this study, but a consistent increase in CD8⁺ T cell expression was observed at the enthesitis in patients with psoriatic arthritis compared with RA patients. Ultrasound-guided biopsy of five sites of acute enthesitis in early spondyloarthropathy confirmed an inflammatory response with increased vascularity and cellular, predominantly macrophage, infiltration.⁸⁰ These findings are consistent with the well-described association of psoriatic arthritis with HLA class I antigens. They also are consistent with the previously described dominance of activated and mature CD8⁺ T cells in psoriatic arthritis synovial fluid samples compared with RA.⁸¹ It is attractive to suggest that enthesially derived antigens might trigger an immune response in adjacent synovial tissue. To date, evidence for this hypothesis has not been found, although this is clearly an area for future study. A search for candidate antigens common to the enthesitis and the skin might be informative.

Cytokines

Synovial explant tissues obtained from psoriatic arthritis joints have been shown to produce higher levels of the T helper type 1 (Th1) cytokines interleukin (IL)-2 and

interferon- γ protein than explants similarly cultured from osteoarthritis and RA patients.⁸² This Th1 lymphocyte profile also has been observed in psoriasis plaques.⁸³ The cytokines IL-1 β and TNF were released by psoriasis synovial explants in high concentrations. In contrast, IL-4 and IL-5 were not identified, but IL-10 was highly expressed in psoriatic synovium, although not in skin. A similar pattern of cytokine production in psoriatic arthritis synovium was shown using immunohistochemical and gene expression techniques.^{84,85} Other innate cytokines, such as IL-18 and IL-15, are present in psoriatic arthritis synovial tissue and are downregulated by methotrexate therapy.

The role of Th17 cells has been explored, and an important immunomodulatory role has been better established in psoriasis than in psoriatic arthritis. Comparison of lesional skin gene expression in responders versus nonresponders to etanercept revealed rapid downmodulation of innate IL-1 β and IL-8 sepsis cascade cytokines in both groups, but only responders downregulated IL-17 pathway genes to baseline levels.⁸⁶ An increase in circulating Th17 cells has been found in psoriatic arthritis,⁸⁷ and an increase in IL-17 has been found in skin, synovial tissue, and synovial fluid of psoriatic arthritis patients.⁸⁸ Further supporting a key role for the Th17 pathway, genetic polymorphisms in key cytokines involved in differentiation of T cells to Th1 and Th17 subtypes, IL-12 and IL-23, have been found to be associated with susceptibility to both psoriasis and psoriatic arthritis,⁸⁹ and inhibition of the common p40 subunit of IL-12/IL-23 has led to clinical improvement in both skin and joint manifestations.⁹⁰

TNF levels are elevated in psoriatic skin, synovium, and joint fluid of patients with psoriatic arthritis.^{82,91} Several lines of evidence support the concept that TNF is an important cytokine in the psoriatic joint. TNF transgenic mice exhibit extensive bone destruction similar to that observed in some psoriatic arthritis patients. In a study of 129 patients with early psoriatic arthritis, patients with erosions were significantly more likely to have the TNF-308 A allele, an allele associated with high TNF production.⁵⁹ As was mentioned earlier, immunohistochemical and gene expression studies have shown marked upregulation of TNF in the psoriatic synovial membrane. Histopathologic analysis of synovial specimens from eight spondyloarthropathy patients, four of whom had psoriatic arthritis, treated with the anti-TNF monoclonal antibody infliximab revealed decreased vascularity, synovial lining thickness, and mononuclear cell infiltration after therapy.^{92,93} In another study, a significant reduction in the quantity of infiltrating macrophages, the CD31⁺ vascular area, α v β 3-positive neovessels/*Ulex europaeus* agglutinin-positive vessels, VEGF and its receptor KDR/flk-1 (VEGFR-2), and SDF-1-positive vessels in psoriatic arthritis synovium was noted after 8 weeks (three infusions) of infliximab treatment.⁹⁴

Matrix Metalloproteinases and Cartilage Destruction

Radiographs of psoriatic joints often reveal cartilage loss manifested as joint space narrowing. Similar to RA, matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs (TIMPs) were identified in psoriatic arthritis synovial lining and sublining layers.^{95,96} In particular,

immunohistochemical studies revealed that MMP-9 localized to blood vessel walls, whereas MMP-1, MMP-2, MMP-3, TIMP-1, and TIMP-2 showed a cellular and interstitial staining pattern in the synovial lining. Serum levels of MMP-3 exhibited a marked and rapid decrease after successful anti-TNF therapy, raising the possibility that this molecule may serve as a biomarker. In another study, similar levels of MMP-1 and MMP-3 mRNA were detected in RA and psoriatic arthritis synovial tissue despite the fact that RA patients exhibited more erosions on plain radiographs.⁹⁷ The elevated ratio of MMPs to TIMP-1 in synovial tissue favored cartilage degradation, although expression of MMPs was not significantly elevated at the cartilage-pannus junction compared with other sites. These reports indicate that MMPs are upregulated in psoriatic arthritis synovium, but their precise functions remain to be defined.

Bone Remodeling

Radiographs of psoriatic arthritis joints can reveal markedly altered bone remodeling in the form of bone resorption (tuft resorption or osteolysis, large eccentric erosions, and pencil-in-cup deformities) and new bone formation (periostitis, spur or enthesophyte formation, bony ankylosis). Important in bone resorption, psoriatic joint biopsy specimens show large multinucleated osteoclasts in deep resorption pits at the bone-pannus junction.⁹⁸ Osteoclastogenesis (differentiation of monocytes into osteoclasts) is a contact-dependent process directed by osteoblasts and stromal cells in the bone marrow. These cells release signals necessary for differentiation of an osteoclast precursor derived from the CD14⁺ monocyte population into an osteoclast.

One of these signals is the receptor activator of nuclear factor κ B ligand (RANKL), a member of the TNF superfamily that binds to receptor activator of nuclear factor κ B (RANK) on the surface of osteoclast precursors and osteoclasts. This ligand-receptor interaction stimulates proliferation and differentiation of osteoclast precursors and activation of osteoclasts. It has been proposed that the relative expression of RANKL and of its natural antagonist osteoprotegerin (OPG) ultimately controls osteoclastogenesis. In psoriatic arthritis synovial tissues, marked upregulation of RANKL protein and low expression of osteoprotegerin were detected in the adjacent synovial lining.⁹⁸ Osteoclasts also were noted in cutting cones traversing the subchondral bone, supporting a bidirectional attack on the bone in psoriatic joints. In addition, osteoclast precursors, derived from circulating CD14⁺ monocytes, were markedly elevated in the peripheral blood of patients with psoriatic arthritis compared with healthy controls. Treatment of patients with psoriatic arthritis with anti-TNF agents significantly decreased the level of circulating osteoclast precursor, supporting a central role for TNF in the generation of this precursor population. Although abundantly expressed, there appeared to be little relationship between expression of RANKL, OPG, and RANK and both systemic and local inflammation,⁹⁹ and also little relationship between the decline in osteoclast precursor numbers and bone marrow edema following etanercept treatment.¹⁰⁰

The mechanisms responsible for new bone formation in the psoriatic joint are poorly understood. Higher circulating levels of bone formation markers, in particular bone

alkaline phosphatase, in psoriatic arthritis patients as compared with RA patients both before and after anti-TNF therapy commenced has been demonstrated (Szentpetery, personal communication). TGF- β and VEGF may be pivotal in this process of new bone formation, given that TGF- β is strongly expressed in synovial tissues isolated from patients with ankylosing spondylitis and synergizes with VEGF to induce bone formation in animal models.¹⁰¹ De Klerck and colleagues¹⁰² showed that the bone morphogenetic proteins (BMPs) BMP-2 and BMP-7 are upregulated in regions of pathologic new bone formation. The same investigators showed that expression of phosphorylated Smad-1 and Smad-5, important signaling molecules downstream of BMP, was markedly increased in regions of new bone formation taken from the calcaneus in a patient with Achilles tendinitis and periostitis. These studies provide evidence that potential mediators of ankylosis and periostitis in the psoriatic entheses and joint include BMP molecules and possibly VEGF and TGF- β . Finally, the Wnt pathway and the balance between Wnt and the Wnt antagonist dickkopf-1 (DKK-1), which binds to the Wnt receptor complex on the surfaces of osteoblast lineage cells, may well be of considerable importance in the disordered bone remodeling found in psoriatic arthritis.

Summary

In considering a model for disease pathogenesis in psoriatic arthritis, we have to try to take into account genetic susceptibility; the role of the environment; cellular immunologic mechanisms; and secreted cytokines, chemokines, and other proteins. For some time, the primary hypothesis has been that psoriatic arthritis is an HLA class I-restricted, antigen-driven immune process (Figure 77-10). Considerable evidence has been presented to support this hypothesis; however, despite careful analysis of T cell receptor phenotype, no antigen-driven process other than that driven by Epstein-Barr virus has been identified.¹⁰³ The potential role of components of the innate immune response, such as Toll-like receptors or cells bearing natural killer receptors, is currently under active investigation. It is possible that the interaction of environmental factors, such as those derived from pathogens or expressed after trauma, with Toll-like receptors in a genetically susceptible individual may set in train intracellular signaling events leading to cytokine release, immune activation, and release of destructive enzymes such as MMPs (Figure 77-11).

TREATMENT

In considering treatment strategies for psoriatic arthritis, the diverse nature of the clinical phenotype (peripheral arthritis, skin and nail disease, axial disease, dactylitis, and enthesitis) may complicate therapeutic decisions because not all treatments are effective for all features, and patients often display a mixture of all of the features simultaneously. GRAPPA published a systematic review of the evidence for treatment strategies in psoriatic arthritis; this review provided treatment guidelines that are currently being revised. The reader is referred to this GRAPPA publication for a detailed review of the evidence; Figure 77-12 is a proposed preliminary algorithm for treatment choices.¹⁰⁴ Treatment

choices may be driven by the disease feature considered most severe at the time of evaluation. Finally, in reviewing the evidence for therapeutic effect presented in the following section, recommendations from the Agency for Health Care Policy and Research were used, whereby interventions are scored by categories of evidence (level 1 through 4) and strength of recommendation (grade A through D).¹⁰⁵

Traditional Agents

Although there is little published evidence of a favorable therapeutic effect in psoriatic arthritis, nonsteroidal anti-inflammatory drugs are most often the agents first used in psoriatic arthritis, whatever the clinical phenotype (level 1b, grade A).¹⁰⁶ Expert opinion supports the use of

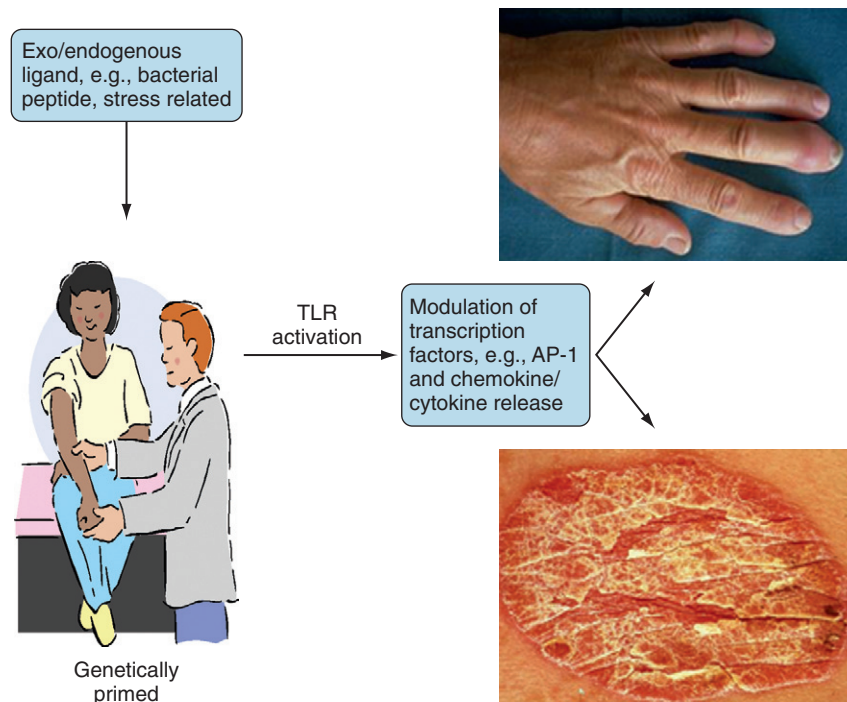

Figure 77-11 Alternative model incorporating new disease pathogenesis concepts. TLR, Toll-like receptor.

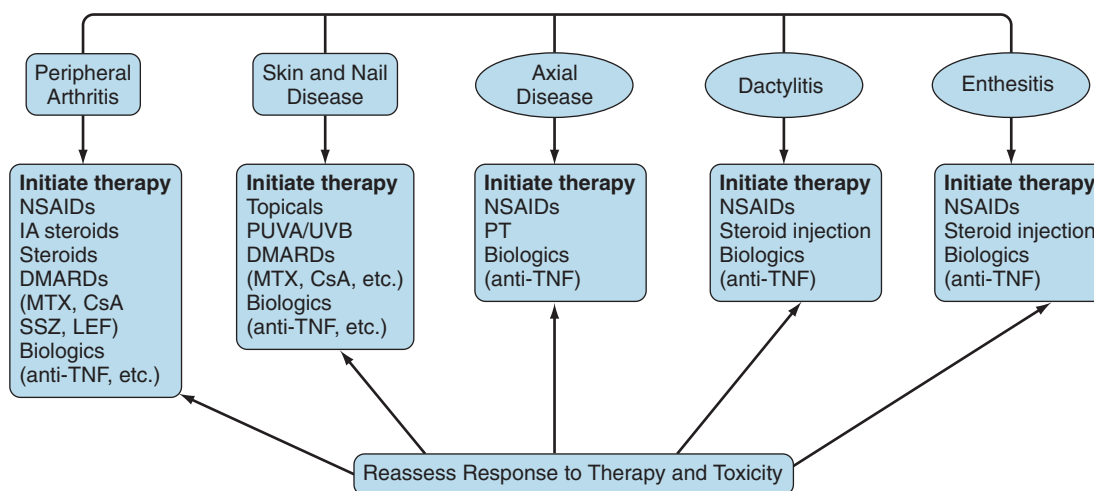

Figure 77-12 Preliminary treatment algorithm for the various clinical manifestations in psoriatic arthritis. CsA, cyclosporin A; DMARDs, disease-modifying antirheumatic drugs; IA, intra-articular; LEF, leflunomide; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; PT, physical therapy; PUVA, psoralen plus ultraviolet A; SSZ, sulfasalazine; TNF, tumor necrosis factor; UVB, ultraviolet B. (From Kavanaugh AF, Ritchlin CT: *Systematic review of treatments for psoriatic arthritis: an evidence based approach and basis for treatment guidelines*, J Rheumatol 33:1417–1421, 2006.)

nonsteroidal anti-inflammatory drugs, although occasional exacerbations of psoriasis have been reported. The use of systemic corticosteroids is not evidence based (level 4, grade D), although 24% of patients in one study were taking prednisolone.¹⁰⁷ Concerns have arisen suggesting that exacerbations of psoriasis may follow corticosteroid withdrawal. No randomized controlled trials have examined intra-articular steroids in psoriatic arthritis or the use of local enthesal or dactylitis injections. Expert opinion indicates that intra-articular steroids can be quite effective, especially in oligoarticular disease, or where localized enthesal involvement is present, as in plantar fasciitis (level 4, grade D). Mild skin disease (PASI <10) is usually controlled with topical steroids or vitamin D derivatives; the latter are best used for maintenance therapy.¹⁰⁸

Systemic therapy is considered in patients with three or more inflamed joints despite conventional therapy, as described previously; persistent or treatment-resistant axial, enthesal, or dactylitic disease, especially where multiple sites are involved; or moderate or severe psoriasis (PASI >10). Randomized controlled trials of disease-modifying antirheumatic drugs (DMARDs) are few and limited by size. Based on evidence and expert opinion, nearly all DMARDs may have small to moderate beneficial effects on peripheral joints, enthesitis, and dactylitis.^{106,109,110} Axial features and nail disease do not seem to respond.¹¹¹ Good or moderate improvements in skin disease have been reported with some of the older systemic agents, such as methotrexate, cyclosporine, sulfasalazine, leflunomide, and acetretrin (all level 1b, grade A).¹⁰⁸

The best evidence for DMARD use comes from studies of peripheral joint disease and of psoriasis. Six randomized controlled trials have studied the use of sulfasalazine in psoriatic arthritis (level 1a, grade A); the largest included 221 patients. Fifty-nine percent of patients achieved a therapeutic response (PsARC), but consistent with other studies, a high therapeutic response (42.7%) was also noted in placebo-treated patients.⁵⁰

Methotrexate remains for many rheumatologists the DMARD of first choice for patients with psoriatic arthritis, but evidence for its use is limited (level 3, grade B). A small, prospective randomized controlled trial concluded that methotrexate was as effective as cyclosporine; another study of 72 patients with active psoriatic arthritis and an incomplete response to methotrexate, in which cyclosporine was added in, showed significant differences only in synovitis as detected by MSUS and PASI score in favor of the combination therapy.^{31,112} Although evidence for methotrexate is lacking, an open study reported significant reductions in synovial cellular infiltration and in cytokine gene expression after 3 months of therapy.⁶⁵ Although evidence suggests that cyclosporine may be as effective as methotrexate, its use is limited because its toxicity profile is considered to be high (level 1b, grade B).¹¹³

Perhaps the best randomized controlled trial in psoriatic arthritis of a DMARD examined the use of leflunomide (level 1b, grade A).¹¹⁴ This trial included 190 patients who received leflunomide or placebo for 24 weeks. Fifty-nine percent of patients treated with leflunomide compared with 30% of patients given placebo met the primary response criteria (PsARC), with significant, although small, improvements in other individual parameters, including joint scores, health assessment questionnaire results, PASI, and Dermatology Life Quality Index scores. Regarding some older DMARDs, such as gold salts and antimalarials, no evidence of treatment benefit has been found; exacerbation of psoriasis has been reported, and these agents cannot be recommended. One small, randomized controlled trial with azathioprine suggested benefit with a reduction in Ritchie score (level 2b, grade B). Finally, apart from the cyclosporine/methotrexate study referred to earlier, little or no evidence suggests that DMARD combination therapy is beneficial or safe in psoriatic arthritis.

With the exception of psoriasis, there is a paucity of evidence that DMARDs are beneficial for the other features of psoriatic arthritis, including dactylitis, axial disease, or

enthesitis. Absence of evidence does not mean absence of an effect, however. Further randomized controlled trials specifically examining these features in psoriatic arthritis are required. In psoriasis, methotrexate and cyclosporine have been shown to be highly and probably equally effective (level 1b, grade A).¹⁰⁸ Adverse effects, in particular with cyclosporine, may limit usage in some patients.

Biologics

The approach to treatment in psoriatic arthritis has changed considerably with the introduction of biologic therapies. As a result of numerous large, well-conducted, randomized controlled trials, accumulating evidence indicates that anti-TNF treatments are effective in controlling peripheral arthritis symptoms and signs, improving quality of life, and preventing radiologic progression (overall level 1b, grade A).¹⁰⁶ Indeed higher rates of Disease Activity Score (DAS)28 remission are found in psoriatic arthritis patients as compared with RA patients after 1 year of anti-TNF therapy.¹¹⁵ Patients receiving 25 mg subcutaneously twice weekly of etanercept showed significant improvement in American College of Rheumatology (ACR)20 responses (59% vs. 15%) at 12 weeks compared with placebo.¹¹⁶ At 12 months, radiographic disease progression (modified total Sharp score) was inhibited in the etanercept group (−0.03 unit) compared with worsening of +1.00 unit in the placebo group.

Although the anti-TNF therapies have not been compared in any study, their effect on peripheral arthritis seems to be similar. Evidence indicates that anti-TNF therapies are also effective for other disease features, such as nail disease, enthesitis, and dactylitis.^{109,110,117} These studies are limited by the absence of a validated instrument to measure these features. With psoriasis, the effects of anti-TNF therapies can be quite dramatic.¹¹⁸ In particular with antibody therapy, highly significant improvements in PASI scores were achieved (e.g., PASI = 75 in 59% of adalimumab-treated patients vs. 1% in placebo-treated patients after 24 weeks; PASI = 90 in 50%).¹¹⁹ Better skin but not articular responses have been demonstrated in etanercept patients treated with 50 mg twice weekly as compared with once weekly.¹²⁰

Alefacept is a fusion protein of soluble lymphocyte function antigen 3 with Fc fragments of immunoglobulin (Ig) G1. Alefacept was the first biologic agent approved for the treatment of moderate to severe psoriasis (level 1b, grade A). Efficacy was dose dependent and slow, but PASI = 75 was achieved in 33% of patients at some point.¹²¹ Alefacept in combination with methotrexate was evaluated in 185 patients with active psoriatic arthritis.¹²² At 6 months, 54% of alefacept-treated patients versus 23% of placebo-treated patients achieved an ACR20 response. Finally, efalizumab, a humanized monoclonal antibody targeting the CD11a component of lymphocyte function antigen 1, has been approved for the treatment of psoriasis, with PASI = 75 achieved in 22% to 39% in randomized controlled trials,¹¹⁸ but this agent has since been withdrawn owing to safety issues. To date, no evidence for a beneficial effect of efalizumab in other psoriatic arthritis joint manifestations has been observed. Finally, inhibition of the common p40 subunit of IL-12/IL-23 has demonstrated good efficacy in

psoriasis,¹²³ and ustekinumab has now been approved for treatment. A phase II clinical trial in psoriatic arthritis suggests reasonable efficacy for joint disease,⁹⁰ but additional studies are required.

Enteropathic Arthritis

FRANK A. WOLLHEIM •
MONIKA RONNEBERGER

KEY POINTS

The gut wall is a leaky barrier exposed to commensal and pathogenic microorganisms.

Microbiota are essential for maturation and regulation of the immune system.

Gastrointestinal lymphoid tissue–microbiota interaction balances between inflammatory defense and tolerance.

Genetic polymorphisms in Crohn's disease can result in relative immune deficiency.

Some types of joint disease in inflammatory bowel disease are genetically determined.

HLA-B27 interacts with non–major histocompatibility complex genes.

Celiac disease is common in adults, 25% of whom have joint manifestations.

Patients with Whipple's disease often present with joint symptoms.

Microscopic colitis is accompanied by extraenteric autoimmune manifestations.

This chapter deals with rheumatic conditions associated with gut pathology, which are commonly designated as *enteropathic arthritis*. People realized centuries ago that dysentery was sometimes followed by arthritis, a condition now known as *reactive arthritis*. Although it is a well-established example of enteropathic arthritis, reactive arthritis is covered in Chapter 76. This chapter covers musculoskeletal problems associated with inflammatory bowel disease (IBD), celiac disease (CeD), and other less common conditions. New insight into gut physiology, its barrier function, regulation of immune responses, and trophic functions is emerging. Knowledge regarding detailed interactions implicated in the generation of joint disease, however, remains incomplete. The fine-tuning of permeability, interactions between gut contents and gut mucosa, the nature of the gastrointestinal-associated lymphoid tissue, and how gastrointestinal-associated lymphoid tissue generates arthritis are at the core of this chapter.

GUT BIOLOGY AND THE MICROBIOTA

KEY POINTS

The gut mucosa is a leaky barrier and is covered by an “unstirred” layer.

Eighty percent of the gut wall consists of immune cells.

Gut permeability is delicately regulated and is disturbed in disease.

The gastrointestinal tract has three major biologic functions: serving as a barrier against hostile environmental factors; affecting fluid and food absorption and excretion of waste products; and producing major trophic host functions. The gut mucosa has an estimated surface area of 300 to 400 m², which is 200 times the body's skin surface area. This mucosa is constantly exposed to potentially harmful environmental agents against which defense is essential, but at the same time tolerance toward a normal microflora must be maintained. In order to fulfill these diverse functions, the gut is an immunologically privileged organ. Disturbances can lead to food allergy or inflammatory bowel disease (Figure 78-1).

The gut epithelium constitutes a so-called leaky barrier. It consists of intestinal epithelial cells including Paneth cells in deep crypts, mucus-secreting goblet cells, M cells, and lymphocytes. It is covered by a thin layer of fluid separated from luminal flow and peristalsis of the intestine, the so-called unstirred layer, which slows down the diffusion of solutes and prevents loss of digestive enzymes. An increased thickness of the unstirred layer may contribute to malabsorption in CeD. Underneath the basal membrane is the lamina propria, which contains immune cells including lymphocytes, dendritic cells, and macrophages (Figure 78-2).¹ The plasma membrane of the epithelial cells is impermeable to most hydrophilic solutes in the absence of specific transporters. The structure of the interepithelial paracellular space consists of the tight junction, the adherens junction, and the desmosome (see Figure 78-2B). The tight junction is considered rate limiting for permeability. A perijunctional actomyosin ring condensation is regulated by myosin light chain kinase (MLCK), which has been shown to have a central role in regulating tight junction transport and in tumor necrosis factor (TNF)-induced permeability increase.² TNF inhibition will influence permeability via inhibition of MLCK transcription. Overexpression of MLCK, on the other hand, results in increased permeability and activation of immune cells in transgenic mice.³ Although initially healthy, these mice were prone to accelerated colitis if challenged.

Na⁺ solutes smaller than 5000 daltons can pass through the epithelium freely, whereas bacterial products and dietary antigens are dependent on active transport mechanisms. Altered gut permeability can be observed in several diseases, among them nonalcoholic fatty liver disease.⁴ In this condition alterations in the zona occludens 1 (ZO1) expression result in perturbation of permeability. Genetic and exogenous factors such as drugs, nicotine, microorganisms,⁵ and cytokines are potential triggers of pathology by influencing paracellular functions in the gut epithelium.

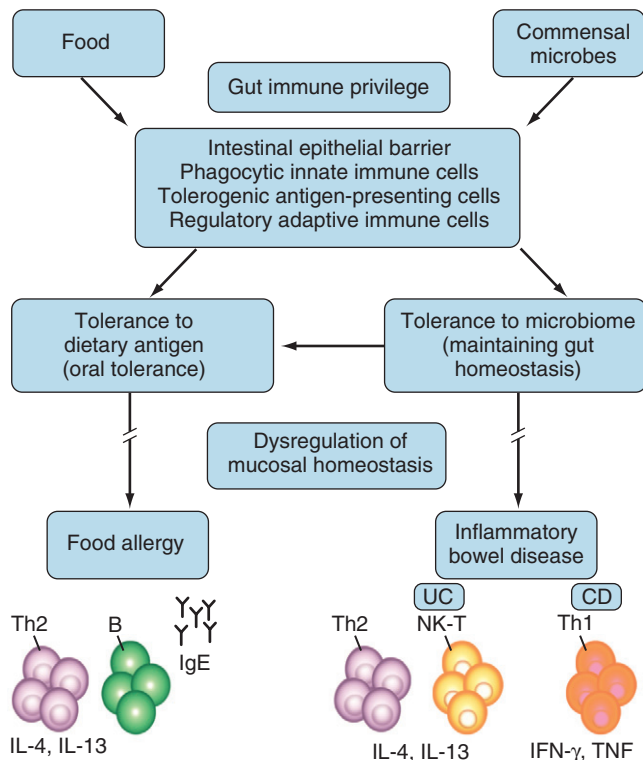

Figure 78-1 Immune privilege in the gut. CD, Crohn's disease; IFN, interferon; IL, interleukin; NK-T, natural killer T cell; TNF, tumor necrosis factor; UC, ulcerative colitis. (From Iweala OI, Nagler CR: *Immune privilege in the gut: the establishment and maintenance of non-responsiveness to dietary antigens and commensal flora*, Immunol Rev 213:82–100, 2006.)

Assessment of mucosal permeability and transport can be achieved by oral feeding of lactalbumin, lactoglobulin, polyethylene glycol particles, ^{51}Cr -labeled ethylenediamine tetraacetic acid (EDTA), and sugars such as lactulose and mannitol, followed by urinalysis. In addition, intestinal permeability and function can be studied by regional perfusion with the help of endoscopic techniques that close off segments of the gut with inflatable balloons.⁶ A study applying enzyme-linked immunosorbent assays to fluid collected by this technique showed marked local immunity to a number of food-related antigens in patients with rheumatoid arthritis.⁷ Ethnic differences in gut permeability have also been described.⁸

The healthy gut harbors a mixture of native bacteria acquired at birth or shortly thereafter that retains a relatively constant composition; it also has a smaller population of transient bacteria of varying composition. The former are essential for health and live in symbiosis; the latter contain potential pathogens. Whereas the stomach and duodenum normally contain less than 10^3 mucosa-adhering bacteria, the number of bacteria increases to 10^4 in the jejunum and 10^7 in the ileum. Most of the latter group comprises gram-negative aerobic species. In the colon, the bacterial density is 10^{12} or more, consisting mostly of anaerobic bacteria. Transit time is fast in the upper gut and slow in the distal gut, but the immunologic impact of the microflora is higher in the proximal parts of the gut.⁹ In other words, the total number of bacterial cells called the *human microbiota* is 10 times that of cells in the body.¹⁰

Analysis of the 16S bacterial ribosomal RNA gene sequence has revealed the presence of a bewildering number of phylotypes in the human gastrointestinal tract, and the number of genes in the microbiome is estimated to be 100 times that of the human genome.¹¹ There is also a high degree of diversity among healthy individuals and some correlation with obesity and other conditions. Most phylotypes have not been cultured, and their functions remain unknown. The potential pathogenicity of individual commensal microbes is demonstrated in a recent paper showing that a single species of segmental filamentous bacteria can trigger autoimmune arthritis in germ-free K/BxN mice by activating Th17 cells in lamina propria.¹²

The normal trophic functions of the gut require this microflora, as demonstrated by host defects in germ-free animals. Bacteria digest food carbohydrates into short-chain fatty acids, which facilitate the absorption of Ca^{2+} , Mg^{2+} , and Fe^{2+} ions; synthesize amino acids and vitamins; and secrete antibacterial protective substances. Some 300 to 500 different species are represented, and the composition is unique for each individual. Figure 78-3 shows some of the common colonic species and their functions.⁹

Gastrointestinal-Associated Lymphoid Tissue and Its Interactions

KEY POINTS

Microbiota are the major regulators of gastrointestinal-associated lymphoid tissue.

Retinoic acid promotes IgA and lymphocyte homing.

Flagellin stimulates dendritic cells to induce Th17 cells.

Vascular adhesion protein-1 is expressed in gut and synovium and is a putative therapeutic target.

Gut lymphocytes express $\alpha 4\beta 7$, $\alpha E\beta 7$, and CCR9, which are important for homing.

Gastrointestinal-associated lymphoid tissue (GALT) is a part of the mucosal immune system, a prominent feature of which is the dominating output of secretory immunoglobulin (Ig)A. This was discovered analyzing tears and saliva in the early 1960s.¹³ GALT is the largest lymphoid organ of the body, constituting 25% of the mucosal mass. Cellular components of GALT are localized in Peyer's plaques, gut lymphoid follicles, lamina propria, and intraepithelial T cells. GALT is part of a complex defense and tolerance regulating system involving specialized dendritic cells (DCs) and intestinal epithelial cells (IECs) (Figure 78-4). Commensal bacteria interact with IECs, which send signals to DCs mediated by anti-inflammatory substances (e.g., thymic stromal lymphopoietin [TSLP]) and to lamina propria DCs. Bacteria also interact directly with DCs by means of their polysaccharide A. A subset of lamina propria DCs expresses CD11b^{hi}, CD11c^{hi}, and Toll-like receptor (TLR5). When exposed to bacterial flagellin, these DCs promote the differentiation of T helper 17 (Th17) cells. These DCs also produce retinoic acid. IEPs also produce retinoic acid from dietary vitamin A, APRIL (a proliferation-inducing

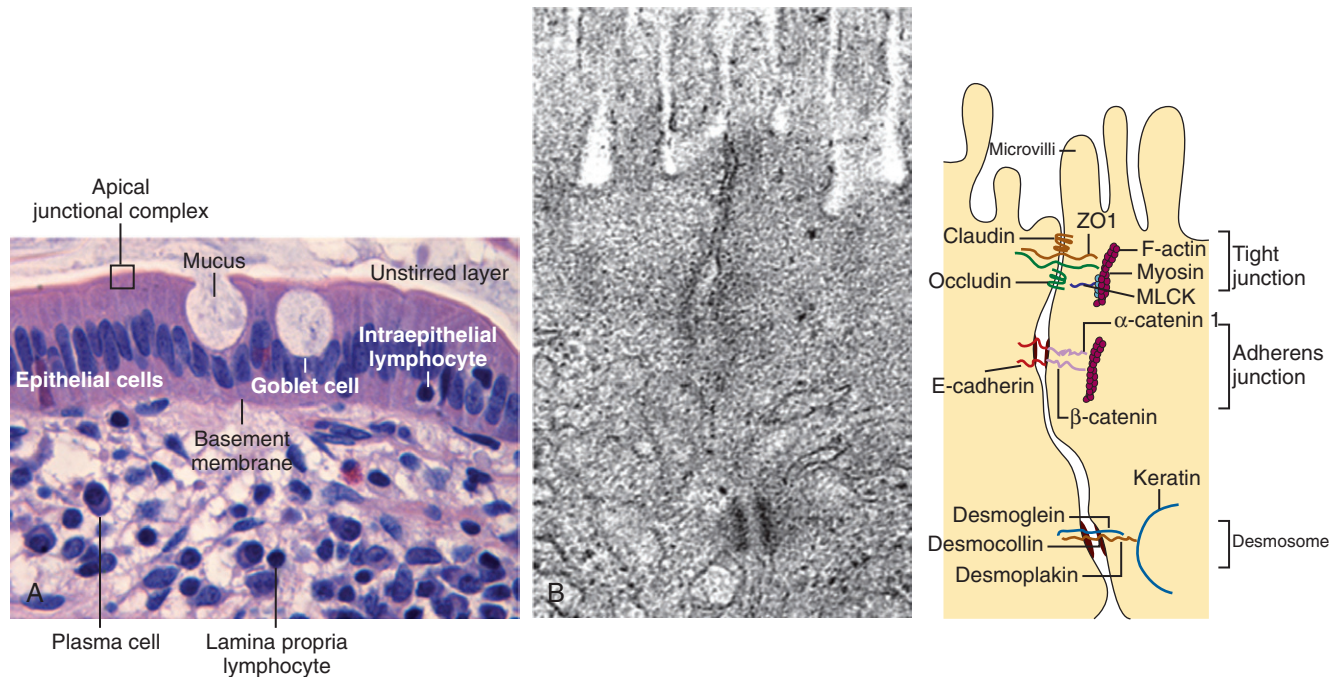

Figure 78-2 Anatomy of the mucosal barrier. **A**, The human intestinal mucosa is composed of a simple layer of columnar epithelial cells, as well as the underlying lamina propria and muscular mucosa. Goblet cells, which synthesize and release mucin, as well as other differentiated epithelial cell types, are present. The unstirred layer, which cannot be seen histologically, is located immediately above the epithelial cells. The tight junction, a component of the apical junctional complex, seals the paracellular space between epithelial cells. Intraepithelial lymphocytes are located above the basement membrane but are subjacent to the tight junction. The lamina propria is located beneath the basement membrane and contains immune cells including macrophages, dendritic cells, plasma cells, lamina propria lymphocytes, and, in some cases, neutrophils. **B**, An electron micrograph and corresponding line drawing of the junctional complex of an intestinal epithelial cell. Just below the base of the microvilli, the plasma membranes of adjacent cells seem to fuse at the tight junction, where claudins, zonula occludens 1 (ZO1), occludin, and F^- actin interact. E^- cadherin, α -catenin 1, β -catenin, catenin $\delta 1$ (also known as *p120 catenin*; not shown), and F^- actin interact to form the adherens junction. Myosin light chain kinase (MLCK) is associated with the perijunctional actomyosin ring. Desmosomes, which are located beneath the apical junctional complex, are formed by interactions among desmoglein, desmocollin, desmoplakin, and keratin filaments. (From Turner JR: *Intestinal mucosal barrier function in health and disease*, Nat Rev Immunol 9:799–809, 2009.)

ligand), and BAFF. Retinoic acid stimulates the expression of the integrin $\alpha 4 \beta 7$ and CCR9, thereby influencing gut-homing lymphocytes.¹⁴ It was recently shown that Wnt- β -catenin signaling is required for the stimulation of expression of anti-inflammatory mediators by intestinal DCs.¹⁵ Bacteria can also penetrate into Peyer's patches (PPs) and create a symbiotic environment with host cells.¹⁶ Cytokines such as interleukin (IL)-10 and transforming growth factor (TGF)- β serve anti-inflammatory functions. Retinoic acid, APRIL, and BAFF contribute to the dominating IgA production in local lymphoid cells. Gut enterochromaffin cells produce 5-hydroxytryptamine, which has anti-inflammatory effects and chromogranins with both proinflammatory and anti-inflammatory effects.¹⁷ Some of these not yet fully understood interactions are depicted in Figure 78-5. Plasma cells in the lamina propria become programmed to produce IgA, but the production is also skewed to formation of dimeric IgA, pIgA, in which the monomers are connected by joint, or J, chains.¹⁸ Intestinal epithelial glycoprotein pIgR, a polymeric immunoglobulin receptor that is also called *secretory component* (SC), is produced in IECs. It is a 100-kD transmembrane receptor for polymeric immunoglobulin, pIgA, and IgM. SC/pIgR is abundantly present in Peyer's patches in the distal ileum. The pIgR in IECs combines with pIgA and to a lesser extent with IgM to form secretory IgA, SIgA, and SIgM, respectively, which are exported into the lumen and constitute a

noninflammatory, non-complement-binding first line of defense. It is estimated that a healthy adult secretes 3 to 5 g of SIgA into the gut daily (Figures 78-6 and 78-7).¹⁸ Breast-feeding provides the newborn with abundant SIgA and SIgM, which confers passive protection and also regulates much of the child's immune system¹⁹ (Figure 78-8).

From the Peyer's patches, primed B lymphocytes disseminate throughout the body's mucous membranes, notably to other parts of the alimentary tract. Primed T lymphocytes also disseminate into the circulation and lymph nodes and home into target organs such as salivary glands (in Sjögren's disease), lungs, and synovium.¹⁹ Vascular adhesion protein-1 (VAP-1) expressed on synovial epithelial cells is involved in lymphocyte homing, and P-selectin is a part of macrophage recruitment. VAP-1 is a bifunctional glycoprotein with both adhesive and amino-oxidative properties.²⁰ Inhibition of this molecule is in development in oncology. A monoclonal antibody is protective against collagen-induced arthritis, and VAP-1 may become a target in the treatment of enteropathic arthritis. Most T lymphocytes in the mucosal lamina propria are CD4⁺, whereas intraepithelial T cells are mostly CD8⁺. Gut-associated lymphocytes preferentially express the integrins $\alpha 4 \beta 7$ and $\alpha E \beta 7$ and the integrin receptor CCR9 on stimulation by intestinal dendritic cells.²⁰

Induction of oral tolerance to type II collagen has demonstrated how GALT activation may ameliorate

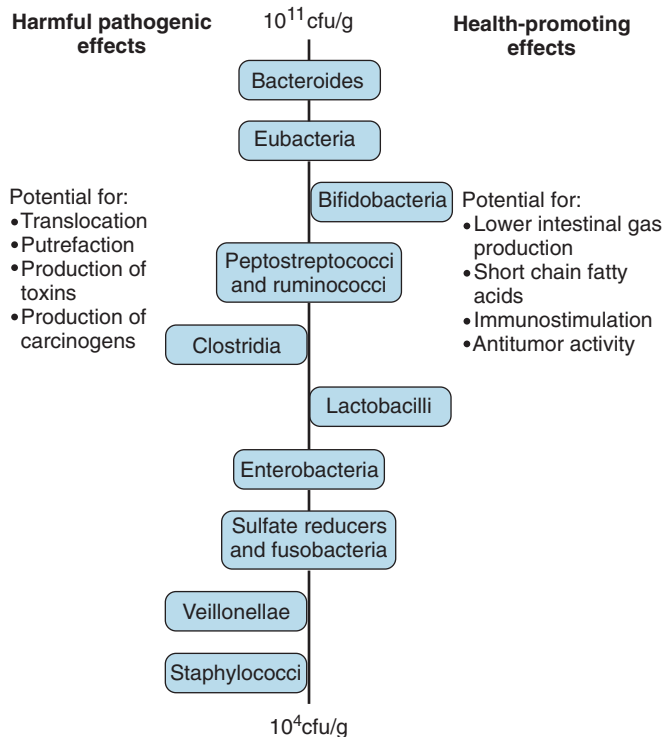

Figure 78-3 Physiologic roles of the intestinal microflora. (From Salminen S, Bouley C, Boutron-Ruault MC, et al: *Functional food science and gastrointestinal physiology and function*, Br J Nutr 80(Suppl 1):S147–S171, 1998.)

inflammatory joint disease (see Figure 78-7).²¹ A chain of events in the pathogenesis of enteropathic arthritis can begin with gastrointestinal infection with the appropriate microorganism in a genetically predisposed patient. This causes local inflammation in the gut mucosa, formation of secretory IgA, increased permeability, absorption of foreign material, and triggering of T lymphocytes. Circulating immune complexes and memory T cells localize to joints and cause synovitis (Figure 78-9). Figure 78-10 summarizes recent understanding of how colonization by segmented filamentous bacteria triggers arthritis in mice.

In conclusion, the gut wall is a highly diversified immunologic, endocrine, and digestive organ. Its interaction with the microbiota potentially mediates both protective and harmful signals (e.g., triggering enteropathic arthritis).

INFLAMMATORY BOWEL DISEASE

Epidemiology

KEY POINTS

The incidence and prevalence of inflammatory bowel disease are higher in developed societies.

Smoking increases the risk in both CD and ulcerative colitis.

Smokeless nicotine (snuff) may be inert or protective.

Ethnic influences are present.

Figure 78-4 Tolerance induction machinery in the gut. Under the influence of commensal bacteria and their products, conditioned intestinal epithelial cells (IECs) constitutively produce anti-inflammatory molecules such as thymic stromal lymphopoietin (TSLP) to limit the inflammation-induced signals, leading to the development of tolerogenic dendritic cells (DCs). Tolerogenic DCs might also be induced by direct stimulation with *Bacteroides fragilis*-derived polysaccharide A (PSA). Once the tolerogenic DCs are developed, they preferentially produce critical factors for the induction of Th2 cells, Tregs, Th17 cells, and IgA⁺ B cells. IECs also produce retinoic acid (RA), a proliferation-inducing ligand (APRIL), and B cell activating factor belonging to the tumor necrosis factor family (BAFF), which probably affect the development of these lymphocyte subsets. Communication among the commensal flora, IECs, and gut immune system is bidirectional, but only a part of the bidirectional communication is shown in this figure. IL, interleukin; TGF-β, transforming growth factor-β. (From Tezuka H, Ohteki T: *Regulation of intestinal homeostasis by dendritic cells*, Immunol Rev 234:247–258, 2010.)

Figure 78-5 Putative role of chromogranins (Cgs) in immune activation and inflammation. Luminal or internal inflammatory stimuli causes alteration in Cgs or Cgs-derived peptides release. They may act locally on Paneth, goblet, and epithelial cells, as well as on immune cells such as macrophages, dendritic cells, neutrophils, mastocytes, and eosinophils. Endothelial permeability, chemotaxis, rolling, smooth muscle contractility, and the enteric nervous system can also be modulated. IL-16, interleukin-16; (–) inhibition; (+) activation. (From Khan WJ, Ghia JE: Gut hormones: emerging role in immune activation and inflammation, *Clin Exp Immunol* 161:19–27, 2010.)

Figure 78-6 Receptor-mediated export of dimeric IgA and pentameric IgM to provide secretory antibodies (SIgA and SIgM) functioning in immune exclusion of antigen (Ag) at the mucosal surface. Polymeric Ig receptor (pIgR) is expressed basolaterally as membrane secretory component (mSC) on secretory epithelial cells and mediates transcytosis of dimeric IgA and pentameric IgM, which are produced with incorporated J chain (IgA + J and IgM + J) by mucosal plasma cells. Although J chain is often produced by mucosal IgG plasma cells (70% to 90%), it does not combine with this isotype and is therefore degraded intracellularly as denoted (±J). Locally produced (and serum-derived) IgG is therefore not subject to pIgR-mediated transport but can be transmitted paracellularly to the lumen together with monomeric IgA as indicated. Free SC (depicted in mucus) is generated when pIgR in its unoccupied state (top basolateral symbol) is cleaved at the apical face of the epithelium-like bound SC in SIgA and SIgM. Commensal bacteria in the right-hand panel are coated in vivo with SIgA, which aids their containment and thereby promotes host-microbial mutualism. (From Brandtzaeg P: Mucosal immunity: induction, dissemination, and effector functions, *Scand J Immunol* 70:505–515, 2009.)

Figure 78-7 Role of Peyer's patch (PP) dendritic cells (DCs) in type II collagen oral tolerance. As a result of repeated oral administration of type II collagen, the production of anti-inflammatory cytokines such as interleukin-10 (IL-10) and transforming growth factor- β (TGF- β) by PP cells is enhanced and the populations of CD11c⁺CD11b⁺DCs and IDO⁺DCs are increased in PP. Then, through DC-T cell interaction, type II collagen inducible CD4⁺CD25⁺Foxp3⁺ and regulatory T cells are generated in the PP. Regulatory T cells generated in the PP move to the mesenteric lymph node and then enter the systemic circulation, where they suppress the systemic immune response to CII. (From Park KS, Park MJ, Cho ML, et al: Type II collagen oral tolerance; mechanism and role in collagen-induced arthritis and rheumatoid arthritis, *Mod Rheumatol* 19(6):581–589, 2009.)

Figure 78-8 Integration of mucosal immunity between mother and newborn. Primed B (and probably T) cells from Peyer's patch migrate via lymph and peripheral blood to the lactating mammary gland, resulting in the presence in breast milk of secretory antibodies (SIgA and SIgM) specific for enteric antigens. GALT, gastrointestinal-associated lymphoid tissue. (From Brandtzaeg P: Mucosal immunity: integration between mother and the breast-fed infant, *Vaccine* 21:3382–3388, 2003.)

Figure 78-9 Immune pathogenesis of enteropathic arthritis.

The prevalence and incidence of IBD are higher in developed countries. Demographics in developing countries, however, show an increase of IBD. Prevalence of Crohn's disease (CD) is not decreasing, although immigration from minor developed countries is accelerating.²² The prevalence of CD and ulcerative colitis (UC) is about equal, and in the United States one observes between 50 and 100 cases per

100,000 population.⁵ In recent years, the incidence of UC has decreased in Western countries, whereas the previously low incidence of IBD in Eastern Europe, South America, and the Pacific has increased.^{22,23} This may be due in part to better reporting. Ethnic affiliation has an influence on the prevalence, although it is still unknown to what extent this is due to genetic or environmental factors. For example, the Jewish population has a higher susceptibility in general but prevalence approaches that of the background population. Romanians have a remarkably lower risk of developing IBD compared with the average Hungarian population.^{24,25} However, ethnic differences in the prevalence of extraintestinal manifestation have not been reported so far.

The incidence of CD and UC in a large Swedish population-based study was 11 per 100,000 and 18 per 100,000 person-years, respectively.²⁶ In this study it was also shown that "ever smokers" had a relative risk of 1.5 (95% confidence interval [CI], 1.2 to 1.8) and 1.3 (1.1 to 1.5), respectively. It was also shown that "ever users" of moist snuff were not at increased risk of developing IBD. Therefore the nicotine component probably does not contribute to susceptibility. On the basis of the immunosuppressive signal mediated by nicotinic acetylcholine α receptors, smokeless nicotine may be innocent or indeed protective.²⁷ The overall concordance in monozygotic twins is 36%, but it is only 16% in UC.²⁸ The onset of disease is highest

Figure 78-10 Effects of colonization of the gut immune system. Segmented filamentous bacteria (SFB) are spore-forming bacteria that are related to the genus *Clostridium*.⁵¹ Inherited from the mother microbiota, SFB develop strong interactions with the ileal mucosa and in immunocompetent mice, the bacteria can largely recapitulate the inducing effects of the whole microbiota on the postnatal maturation of the gut immune system. SFB induce the production of Reg III β / γ microbicidal peptides,^{23,45} which protect against colonizing pathogens.⁴⁶ Additionally, SFB simultaneously activate strong secretory IgA responses,⁴⁴ induce the recruitment and activation of cytotoxic intraepithelial lymphocytes (IELs), and drive various T cell responses including a robust T helper 17 (Th17) cell response.^{28,45} In immunocompetent mice, SFB-induced proinflammatory and regulatory responses balance each other, which results in physiologic inflammation that strengthens the gut barrier. By contrast, colonization by SFB promotes the development of colitis in severe combined immunodeficient (SCID) mice that have been reconstituted with effector T cells.⁵² Intestinal colonization by SFB can also promote the development of inflammatory diseases outside of the gut. SFB promote arthritis in autoimmune nonobese diabetic (NOD) mice that express a transgenic T cell receptor (TCR) that is specific for a self-peptide (known as K/BxN mice), an effect ascribed to the induction of Th17 cells.⁵⁴ SFB also enhance the severity of myelin oligodendrocyte glycoprotein (MOG)-induced experimental autoimmune encephalomyelitis (EAE). These aggravating effects may reflect the strong adjuvant properties of SFB. (From Cerf-Bensussan N, Gaboriau-Routhiau V: *The immune system and the gut microbiota: friends or foes?* Nat Rev Immunol 10(10):735–744, 2010.)

Table 78-1 Extraintestinal Manifestations of Inflammatory Bowel Disease

Feature or Disease	Crohn's	Ulcerative Colitis
Peripheral arthritis	≈15%	≈10%
Axial or sacroiliac arthritis	≈15%-20%	≈10%-15%
Septic arthritis	Rare	Not reported
Skin		
Erythema nodosum	Up to 15%	<15%
Erythema multiforme	Rare	?
Pyoderma gangrenosum	0.5%-2%	0.3%-0.4% in severe disease
Aphthous ulcers	Rare	1%-8%
Nephrolithiasis (oxalate)	<15%	?
Amyloidosis	Very rare	Not reported
Liver disease	3%-5%	7%
Uveitis	13%	4%
Vasculitis	Takayasu's	<5%
Clubbing of fingers	Yes	1%-5%
Increased prevalence of asthma	Yes	Yes
Increased prevalence of multiple sclerosis	No	Yes

between 15 and 30 years of age, but IBD can start at any age. CD has a second peak later in life. There are no marked sex differences of IBD. Joint involvement has been reported in up to 25% of patients.⁶ Lower figures were reported from a large population-based Canadian study,²⁹ but the study excluded peripheral arthritis, which may explain why less than 10% of patients had "arthritis." Interestingly, asthma and multiple sclerosis were overrepresented in two studies of extraintestinal autoimmune manifestations of IBD (Table 78-1).³⁰

Genetics

KEY POINTS

At least 30 genetic associations have been identified in CD, and several occur in UC.

***NOD2* (previously known as *CARD15*), *IRGM*, and *ATG16L1* are associated with DCs.**

***IL23R* and *MDR1* are associated with both CD and UC.**

***IL23R* deletion protects against colitis in mice.**

CD has features of defective intracellular microbial handling.

Etiopathogenic research regarding IBD is in an active stage of development. New technology including genome-wide association studies (GWAS) has identified at least 31 genes showing replicated associations with CD³¹ and a similar number for UC.³² Approximately half of these associations are shared by both diseases. The strongest associations apart from human leukocyte antigen (HLA) are with the *NOD2* (formerly known as *CARD15*) gene on chromosome 16 and the *IL23R* on chromosome 1. *NOD2* and *NOD1* are cytosolic sensors for the bacterial peptidoglycan muramyl dipeptide and trigger the synthesis of antibacterial α -defensins.^{33,34} Reduced mucosal expression of these defensins is found in

patients with CD.³⁵ *IL23* signaling can result in activation of Th17 cells in the gut. The importance of *IL23* is supported by the finding that *IL23R* $-/-$ mice are resistant to induction of colitis.³⁶ Also, *IL23* is upregulated in patients with CD.³⁷ Another association is found with the transcription factor *STAT3*, which is involved in Th17 activation. *STAT3* is present on innate and reactive immune cells and is present in increased amounts in the gut mucosa.³⁸ Another confirmed genetic association is that with *ERAP1*, an endoplasmic reticulum aminopeptidase previously known as *ARTS1*.³⁹ *ERAP1* functions by trimming the length of peptides before loading into the groove of HLA, and therefore it could play a role in the triggering of immune reactions in various locations such as gut and joint. A recent Spanish study looked at the Fc receptor gene *FcRL-3*, which is associated with susceptibility to RA, and found an association with peripheral arthritis in CD. Although this needs replication in other studies, it may indicate an example of a gene combination influencing disease phenotype.⁴⁰ However, it is clear that no single gene or combination of genes alone can account for manifest IBD and clearly the intestinal microflora remains a major suspect as contributor to the cause of IBD, although final proof is lacking. Experimental models of IBD require presence of gut bacteria. Postoperative therapy with metronidazole has prolonged the time to relapse.¹⁴ Whereas *CARD15* mutations were present in 43% of patients in the initial French study,⁴¹ later population studies found a much lower prevalence in northern European populations and no correlation in Asians. *CARD15* mutations are not related to susceptibility in the United States. High expression of *CARD15* messenger RNA has been found in the small intestine, and it is believed to be a regulator of nuclear factor κ B (NF κ B) signaling after the engagement of TLRs. *IBD3* on chromosome 6 has shown the most constant association with IBD, and *HLA-DRB1*0103* has been linked to severe UC in several studies.²⁰ Further, a TNF microsatellite gene factor was associated with CD but not with UC. *HLA-DR2* and *DR3* associations have been linked to UC but not to CD.

Mutations of the detoxifying ATP-binding cassette, subfamily B, member 1 gene (*ABCB1*), also known as multidrug resistance 1 gene (*MDR1*), are strongly downregulated in unaffected colonic tissue of both CD and UC. *TLR4* and *TLR5* associations have been identified in several populations; this may be of special interest because they act in synergy with *CARD15* and *CARD4* in the induction of proinflammatory cytokines. TLR inhibitors are being investigated for therapeutic efficacy. Recently, researchers found a role for a virus as the contributing trigger in gene-manipulated mice, when mice with a disrupted autophagy gene, *ATG16L1*, were infected with a specific strain of murine norovirus and developed CD-like disease.³⁷

Pathogenesis

CD and UC are clinically distinct entities with a different pathogenesis, but genetic evidence also shows common features. Both are familial, but hereditary factors are more important in CD, according to twin studies. Whereas the entire gut wall is involved in a patchy way in CD, diffuse mucosal pathology is typical of UC. T lymphocyte proliferation and cytokine generation are also different. In CD, a

Th1 response dominates,⁴² but no such dominance has been documented for UC. Increased amounts of proinflammatory cytokines, TNF, interleukin (IL)-1 β , IL-6, IL-17, and IL-8, are released locally in both diseases (see Figure 78-1).⁴³

The interplay between the intestinal microflora and genetic host factors is disturbed in IBD. The microbial contribution is still largely unclear, but animal work indicates that parts of the normal gut flora may be involved. In addition, pathogenic organisms such as *Clostridium difficile* have been linked to exacerbations of IBD.⁴⁴ As discussed earlier, genetic factors related to both innate and adaptive immunity are involved in susceptibility to IBD. Experimental work with transgenic animals transfected with human HLA-B27 and β_2 -microglobulin has shown that certain strains of conventional mice and rats develop spondyloarthropathies, whereas identical animals in a germ-free environment are protected.^{45,46} In human IBD, HLA-B27 remains a strong predisposing factor, but only in those individuals with spinal joint involvement. Jejunal fluid from patients with ankylosing spondylitis (AS) and rheumatoid arthritis collected with the closed-segment endoscopic technique contained antibodies against *Klebsiella pneumoniae*, *Escherichia coli*, and *Proteus mirabilis*.⁵ A disturbed and augmented local immune response in parts of the gut against a variety of microorganisms is emerging as a prevalent feature of several chronic joint diseases, but it has not been examined in IBD with this endoscopic technique. The viral contribution cited earlier indicates an important role for Paneth cells and disturbed autophagy in the pathogenesis.⁴⁷

Gene manipulation in mice indicates that IL-2, IL-10, and transforming growth factor (TGF)- β may be protective factors and that HLA-B27 may influence cytokine expression.⁴⁸ Altered cytokine balance in the gut mucosa may be an important contributing pathogenic factor.

Increased gut permeability has already been alluded to as an important factor in pathogenesis.⁶ Bacteria recovered from the gut lumen in IBD are covered by immunoglobulin, part of which is circulatory IgG.⁴⁹ Increased leakage of tissue fluid from the inflamed mucosa allows the egress of complement-binding IgG, which may contribute to inflammation and further augment permeability. The altered immune response to bacteria differs between CD and UC.⁵⁰ Increased gut permeability in IBD is under genetic influence. Basal permeability was normal in a study of relatives of patients with CD, but it became abnormally increased after the ingestion of acetylsalicylic acid.⁵¹ Environmental influences on permeability may be partly mediated by bacterial endotoxin. An in vitro perfusion study on rat gut showed that serosal rather than mucosal application of endotoxin impairs the barrier.⁵² Absorbed bacterial material could therefore add to an already damaged barrier.

Clinical Features

KEY POINTS

Peripheral arthritis in CD and UC occurs in two distinct forms.

Enthesitis pain is more pronounced than in AS.

Sclerosing cholangitis develops in 5% of IBD.

Table 78-2 Distinct Features of Inflammatory Bowel Disease

Feature	Crohn's	Ulcerative Colitis
Replicated non-HLA genetic associations	CARD15/NOD2, IRGM, ATG16L1, IL23R	IL23R
Concordance in monozygotic twins	36%	19%
Non-HLA genes	Several	Several
Gut permeability sensitive to acetylsalicylic acid on genetic base	Yes	?
T lymphocyte response in gut	Th1, Th17 (interferon- γ ↑)	No Th1-Th2 imbalance, Th17
Fas ligand expression	No	Yes
Effect of smoking	Negative	Negative
Correlation of gut activity to arthritis symptoms	No	Yes
Intercellular adhesion molecule-1 antisense therapy	Beneficial	No response (?)
Response to anti-tumor necrosis factor therapy	Well established	Probably effective

Although CD and UC are clinically distinct entities, they share many features (Table 78-2). Spinal involvement occurs in 10% to 20% of cases and may be the only articular manifestation or accompany oligoarthritis.⁵³ Spinal involvement is often silent, so its prevalence is underestimated; it may precede the onset of IBD or appear later.⁶ In contrast to AS, there is an equal sex distribution. In general, the involvement is similar to or identical with that in classic AS, although small differences have been found.⁵⁴ Changes in enteropathic disease tended to be milder, squaring was more prevalent, and Romanus lesions were rare. The majority of radiographic features were similar. As noted, spinal symptoms may be mild or absent, but when present, they do not correlate with intestinal symptoms. The issue is complicated by the association of AS with silent CD, as diagnosed by biopsy.⁵⁵ In full-blown IBD-related AS, the prevalence of B27 is between 50% and 70%, which is lower than in AS not associated with IBD.⁶

Between 5% and 15% of patients in most studies develop peripheral arthritis, slightly more often in CD than in UC (Table 78-3). CD patients with large bowel disease ($\approx 70\%$)

Table 78-3 Peripheral Joint Disease in Inflammatory Bowel Disease

Feature	Type II (>5 Joints)	Type I (<5 Joints)
Ulcerative colitis	3% of all UC; 3% of all CD	2% of all UC; 5% of all CD
Crohn's disease	6% of all UC; 0% of all CD	4% of all UC; 6% of all CD
Clinical course	Self-limited arthritis	Persistent arthritis
Course of IBD	Relapsing in < 85%	Relapsing in 30%-40%
MHC association	HLA-B27, B35, DRB1*0103	HLA-B44

CD, Crohn's disease; HLA, human leukocyte antigen; IBD, inflammatory bowel disease; MHC, major histocompatibility complex; UC, ulcerative colitis.

Figure 78-11 Articular distribution of peripheral arthropathies in inflammatory bowel disease. CD, Crohn's disease; DIP, distal interphalangeal joint; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; PIP, proximal interphalangeal joint; UC, ulcerative colitis. (From Orchard TR, Wordsworth BP, Jewell DP: *Peripheral arthropathies in inflammatory bowel disease: their articular distribution and natural history*, Gut 42:387, 1998.)

and intestinal complications, such as fistulas or abscesses, are more likely to develop peripheral arthritis than patients with disease limited to the ileum.

IBD arthritis is often nondestructive and reversible, but erosive changes may also occur. Limited histopathologic evidence indicates the presence of granulomas in CD and nonspecific synovitis in UC.⁶ In CD patients, rapidly destructive septic arthritis has been reported in the hip. Joint symptoms tend to coincide with gut activity in UC but not in CD. Total colectomy is associated with remission of arthritis in half the patients with UC, but paradoxically, arthritis may also begin after surgery.⁵⁶ This may represent a form of bypass arthritis and is related to altered gut microbiology in a blind loop.

On the basis of examination of about 1500 patients with IBD, an important distinction was made between two forms of peripheral arthritis⁵⁷ (Figure 78-11). Oligoarthritis, or type I, affects fewer than five joints, whereas polyarthritis, or type II, involves more than five joints. The highest prevalence was found in metacarpophalangeal, proximal interphalangeal, knee, and ankle joints. Shoulder involvement was more common in UC, but joint involvement was otherwise strikingly similar. The majority of type I arthritis cases were acute and resolved within 6 weeks, whereas the type II cases persisted.⁵⁸ Type I arthritis was 12 times more prevalent in carriers of the rare *HLA-DRB1*0103* allele, type II arthritis was associated with *HLA-B44*, and sacroiliitis in CD was associated with *CARD15* polymorphisms.⁵⁹ This is an example of genetic influence on disease phenotype and may be a clue to pathogenesis.

Clubbing of fingers, uveitis, and skin manifestations are other extraintestinal manifestations of IBD, with a higher frequency in CD. Erythema nodosum, which is usually self-limited, is most frequent in young female patients with UC. Pyoderma gangrenosum is a more severe, painful, ulcerating skin reaction that is frequently associated with systemic disease⁶⁰ (Figure 78-12). In a series of 86 patients with pyoderma gangrenosum seen at the Mayo Clinic between 1970 and 1983, 31 had IBD.⁶ Erythema nodosum, uveitis, and

peripheral arthritis commonly occur together in IBD and have been linked to *HLA-DRB1*0103* and TNF gene polymorphism.⁶¹ Uveitis is also a feature of other spondyloarthropathies such as AS and reactive arthritis. In IBD, however, uveitis is more often bilateral, and the tendency toward chronicity is more pronounced.^{62,63} Up to 5% of the patients with UC and CD can develop primary sclerosing cholangitis (PSC), a progressive liver disease that can lead to end-stage liver fibrosis.^{64,65} The risk of developing colorectal cancer is increased in IBD and related to the extent of the colonic involvement and disease duration. Colorectal cancer mortality has decreased significantly in the past few decades, however, due to better surveillance and earlier diagnosis.^{66,67}

Diagnosis

Because of the lack of specific tests to confirm a suspicion of IBD-related arthritis, a careful history and clinical examination, supplemented by imaging, are the principal

Figure 78-12 Pyoderma gangrenosum in a case of Crohn's disease. (From Rothfuss KS, Stange EF, Herrlinger KR: *Extraintestinal manifestations and complications in inflammatory bowel diseases*, World J Gastroenterol 12:4819–4831, 2006.)

diagnostic tools. Arthropathy can precede intestinal symptoms in a subgroup of patients, and thus colonoscopy with histologic exploration can be informative regarding the origin of occurring joint symptoms. Fecal calprotectin has emerged as a sensitive screening test for IBD and helps to select cases for endoscopic exploration.⁶⁴ As mentioned earlier, genetic mapping has shown interesting clinical correlates, but genotyping is not part of the routine clinical workup at present, except perhaps for *HLA-B27*. Stool cultures should be performed when infection with special pathogens is suspected. In patients with apparent IBD and monoarthritis, joint aspiration is important to exclude septic arthritis, especially before starting immunosuppressive therapy.

Treatment

KEY POINTS

Symptomatic treatment of joint disease in IBD is often adequate.

In disease-modifying antirheumatic drug-unresponsive disease, TNF inhibitors may work.

Interferon- γ , IL-23, and IL-6 are potential new targets.

Probiotic efficacy is unproved.

Joint manifestations are considered secondary to active IBD. Current dogma states that treating the latter will benefit the former, but there is no rigorous proof. Placebo effects account for perhaps 20% of the treatment response in IBD; therefore only placebo-controlled evidence can be trusted. To bring into focus the arthritic discomforts, symptomatic relief is still the main target because in general, IBD-associated arthritis is nondestructive. Pain control with nonsteroidal anti-inflammatory drugs (NSAIDs) is a possible problem owing to their potential induction of flares. However, they are widely used, often well tolerated, and remain an important tool, especially in patients with primary involvement of the spine or enthesitis. Experience with the selective cyclooxygenase-2 inhibitor celecoxib, although limited, has failed to show improved gastrointestinal tolerance in comparison with other NSAIDs.⁶⁷

Sulfasalazine and its derivative 5-acetylsalicylic acid (5-ASA) inhibit the function of NF κ B, and several studies have shown the efficacy of these drugs compared with placebo in UC but not in CD.⁵ Glucocorticoids are effective in both forms of IBD, although the response of uveitis to topical therapy with glucocorticoids may be less prompt than in other forms of uveitis.⁶ In patients with oligoarthritis, intra-articular glucocorticoid injection can be effective and safer than oral administration. Azathioprine has been widely used to maintain remission in IBD. It has proven long-term efficacy in both UC colitis and CD, according to a large European study.⁶⁸ It should not be combined with 5-ASA owing to a pharmacokinetic interaction.⁶⁹ If azathioprine is not tolerated, methotrexate is recommended under frequent monitoring for signs of hepatotoxicity.

TNF inhibition with infliximab results in remission of gastrointestinal manifestations in close to 60% of patients

Table 78-4 Approved Biologics for Crohn's Disease (as of 2012)

United States	European Union	Switzerland
Infliximab Adalimumab Certolizumab pegol Natalizumab (limited)	Infliximab Adalimumab	Infliximab Adalimumab Certolizumab pegol

with CD, as confirmed in several placebo-controlled studies.⁷⁰ Similar data are available for adalimumab, even in patients with previous infliximab exposure⁷¹ and certolizumab pegol.⁷² Interestingly, etanercept, which is not beneficial for intestinal manifestation, seems to be effective for spinal and peripheral involvement. An overview of approved anti-TNF therapy in CD is given in Table 78-4.

Infliximab was found to be superior to placebo in UC patients resistant to conventional drug therapy, although the evidence is less robust if compared with glucocorticoid therapy.⁷³ However, for UC, infliximab remains the only currently approved TNF-inhibiting treatment. A recent Swedish study shows higher survival on drug therapy among patients of male sex and with peripheral arthritis.⁷⁴

Natalizumab, targeting $\alpha 4$ integrin, has shown promising effects in both multiple sclerosis and CD. However, enthusiasm was reduced after the occurrence of three cases of lethal progressive leukoencephalitis.⁷⁵ The drug is still in limited use. ABT-874/J695, an anti-interleukin 12/23 antibody and ustekinumab, directed against the shared subunit p40, are more effective compared with placebo in first studies with patients suffering from CD.^{76,77}

Currently anti-interferon (IFN)- γ antibodies such as fontolizumab are being investigated for their efficacy in CD, and early data suggest a significant response compared with placebo.⁷⁸ In a pilot study, tocilizumab, an anti-interleukin-6 receptor monoclonal antibody, showed significant but not complete response in patients with active CD.⁷⁹ Probiotics, although commercially promoted, have not been proved effective in IBD.⁸⁰ Metronidazole, ciprofloxacin, and other poorly absorbed broad-spectrum antibiotics have been widely tested in controlled studies, but there is no convincing evidence that they are better than placebo and they are usually inferior to glucocorticoids.⁸¹

Outcome

No prospective studies have addressed the outcome of arthritis complicating IBD. Central and peripheral arthritis shares most features with spondyloarthropathies not associated with or with silent IBD.

BRUCELLA ARTHRITIS

Epidemiology

Brucellosis has been eradicated in Western Europe and North America but is still a major zoonosis in areas of South America, the Middle East, India, and other places where goat and sheep farming is practiced and poverty is prevalent. With increased global travel, sporadic cases can be expected

in Europe and the United States. In endemic areas, the reported incidence is between 1 and 200 cases per 100,000.⁸²

Cause and Pathogenesis

Brucella are small gram-negative bacteria that infect macrophages and are harbored in the liver, spleen, and bone marrow; from there, they can spread to joints. The four species causing human disease are *Brucella melitensis*, *Brucella abortus*, *Brucella suis*, and *Brucella canis*. *Brucella* arthritis is thought to be reactive on the basis of the failure to grow microorganisms from joint fluid and the poor response to antibiotic therapy, but this has never been proved.⁶

Clinical Features and Diagnosis

Brucellosis causes arthritis in about one-third of cases. The main locations are the spine in adults and the peripheral joints in children and adolescents. Knees, hips, and ankles are the dominant peripheral locations. Sacroiliitis can be extremely acute and painful. Rising titers of serum antibodies and a confirmatory culture solidify the diagnosis. Case reports describe septic prepatellar bursitis⁸³ and olecranon bursitis⁸⁴ and indicate that fluid from these lesions can be diagnostic.

Treatment and Outcome

Rifampicin 600 to 900 mg and doxycycline 200 mg daily for at least 6 weeks are recommended by the World Health Organization, but other combinations have been tried.⁸² The arthritis can become destructive unless treated early. Spinal stenosis may be a complication.

BYPASS ARTHRITIS-DERMATITIS SYNDROME

Epidemiology

Improved surgical techniques for overweight treatment have eliminated a major cause of bypass arthritis-dermatitis syndrome. It may occur as a rare complication in gastrointestinal diseases with defective peristalsis, systemic sclerosis, and IBD, particularly after colorectal surgery.⁶

Cause and Pathogenesis

Bacterial overgrowth in a blind loop is the likely cause. The formation and absorption of complement-binding immune complexes with increased gut permeability are contributing factors in pathogenesis.

Clinical Features and Diagnosis

The main features seen in patients in the 1970s were an intensely painful oligoarthritis of the large and small joints and the spine, without structural changes, and a recurrent papulopustular rash (Figure 78-13). Today, gastrointestinal dysfunction in combination with painful, nondestructive oligoarthritis and intermittent papular skin rash may be encountered.

Figure 78-13 Relapsing pustulosis in a patient with bypass arthritis-dermatitis.

Treatment and Outcome

Correction of gastrointestinal function, administration of nonresorbed antibiotics such as neomycin, and symptomatic pain relief are the principal therapeutic options. Prolonged complaints have been reported, but cure is the rule.

CELIAC DISEASE

Epidemiology

CeD is a common condition with a global distribution. It used to be considered most prevalent in children, but new evidence shows that it is even more common in adults. Intestinal symptoms may be minimal or absent; consequently, published prevalence figures of 1% may be too low.^{6,85,86} In juvenile idiopathic arthritis CeD has been found in 6% to 7% of cases.⁸⁶

Cause and Pathogenesis

CeD is caused by an immune reaction to partly digested wheat gluten by T lymphocytes in the gut of genetically HLA-DQ2–positive or HLA-DQ8–positive individuals. A seminal observation was the finding that tissue transglutaminase is the major autoantigen in CeD.⁸⁵ It was shown in 2002 that dietary gluten is partly digested by gastric enzymes to generate a stable 33–amino acid peptide that is deamidated by tissue transglutaminase.⁸⁷ The peptide is then presented in the context of HLA-DQ2 or HLA-DQ8 to CD4⁺ T cells, resulting in IFN- γ release and inflammation, altered gut permeability, and eventually villus atrophy. Autoantibodies against tissue transglutaminase are also formed.⁸⁵ CeD can now be considered as a systemic disease that may involve GI-related pathology, as well as endocrine, skin, locomotor, and neural abnormalities (Figure 78-14).⁸⁶

Clinical Features and Diagnosis

Only two-thirds of patients present with diarrhea or irritated bowel symptoms. Nonspecific signs such as fatigue, headache, and arthralgias may occur and delay a correct

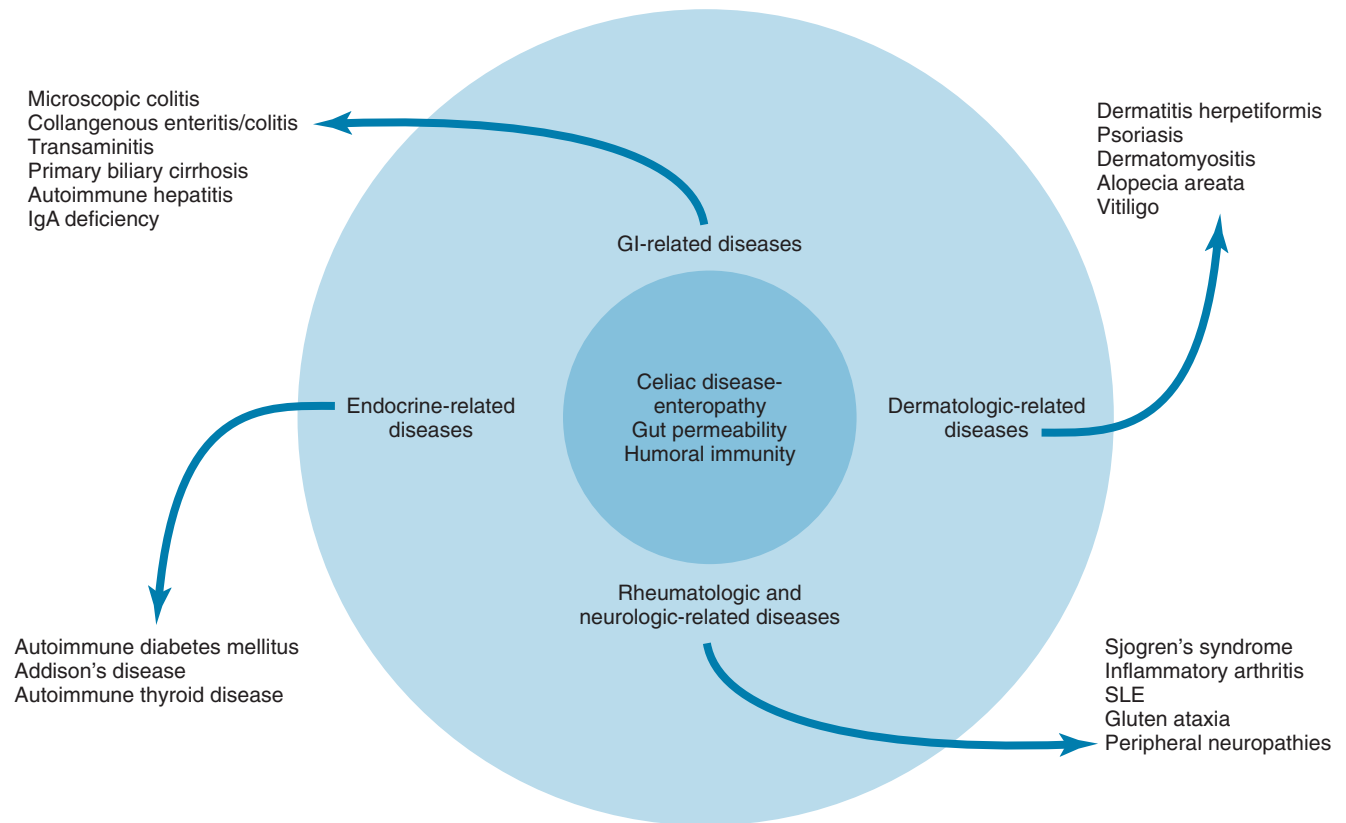

Figure 78-14 Celiac disease as a multiorgan systemic condition. GI, gastrointestinal; SLE, systemic lupus erythematosus. (From Barton SH, Murray JA: *Celiac disease and autoimmunity in the gut and elsewhere*, *Gastroenterol Clin North Am* 37(2):411–428, 2008.)

diagnosis.⁸⁶ CeD is a systemic disease that can involve type I diabetes, anemia, osteoporosis, neuropathies, and joint symptoms in up to 25% of patients.⁸⁸ This can be an asymmetric oligoarthritis or polyarthritis, and axial involvement is common. Arthritis may be the presenting symptom of the disease.⁸⁹

In addition to small bowel biopsy, the diagnosis can be established by assaying for the presence of serum for IgA antitissue transglutaminase antibodies and IgA antiendomysial antibodies.⁹⁰

Treatment and Outcome

Elimination of gluten from the diet is the rational therapy and is often the only one required. In addition, various experimental approaches have been discussed but are not yet supported by data. These include the administration of IL-10 to boost regulatory T cells, the induction of tolerance by nasal application of gluten peptides, and gene therapy. No specific therapy has been established for the joint problems.

Children with verified CeD still have abnormal mucosa in adulthood and must continue the dietary restriction. There are no outcome reports dealing with joint involvement.

WHIPPLE'S DISEASE

Epidemiology

Whipple's disease is a rare condition. Incidence and prevalence figures are unknown. A retrospective French study identified 52 patients, 73% of whom were men.⁶

Genetics and Pathogenesis

Whipple's disease, or intestinal lipodystrophy, as it was initially called in 1907,⁶ is an intestinal infection with a unique microorganism called *Tropheryma whipplei*, belonging to the Actinomycetes family. The organism has been found in sewage, but the source of infection in humans is not known. Six different genotypes have been confirmed in culture from diseased tissue.⁹¹

The organism lives in macrophages, and these elicit a skewed lymphocyte response, with suppressed Th1 dominating Th2 cells. Expression of the cytokine IL-16 stimulates growth of the pathogen.⁹² In vitro monocytes from patients with Whipple's disease express CD163, possibly explaining a reduced oxidative impact against *T. whipplei*.⁹³ A correlation between different clinical manifestations and variable genotypes of the bacterium has not been identified, and host factors seem to be crucial for the kind of

manifestation.⁹⁴ Altered gut permeability may be implicated in joint involvement. In a cohort of 122 European patients, an association between HLA alleles *DRB1**13 and *DQB1**06 and Whipple's disease was found, supporting a genetic contribution to susceptibility.⁹⁵

Clinical Features

The disease can have many faces and may remain undiagnosed for many years. Recurrent fever; malaise; hematologic, pulmonary, and cardiac disturbances; and neurologic and ophthalmic symptoms are sometimes present and misinterpreted. Articular symptoms, however, are the presenting feature in 67% of cases, compared with intestinal symptoms in only 15%. Eventually, 83% of patients develop diarrhea, abdominal pain, and malnutrition. Arthralgias and arthritis are most commonly seen in knee joints but can localize in any peripheral joint, as well as in spinal joints and disks. Sacroiliitis has been described.

Diagnosis

The diagnostic test of choice rests on immune histology, with the occurrence of periodic acid–Schiff–positive material, an abundance of CD68⁺ macrophages, and staining with antisera specific for *T. whipplei*. Quantitative PCR of saliva and stool has been suggested as a noninvasive screening method.⁹⁶ PCR of cerebrospinal fluid can detect central nervous system involvement.⁹⁷ The organism can grow out in culture, which takes an average of 30 days. In one study, only 2 of 10 small bowel specimens were culture positive; the yield is higher using sterile cardiac or nerve tissue.⁹¹ Culture therefore remains a research tool.

Treatment

No randomized, controlled studies are available. Initial treatment should be ceftriaxone for 2 weeks to ensure entrance into the central nervous system. Then oral trimethoprim-sulfamethoxazole is administered for a prolonged or indefinite period. In case of intolerance or lack of efficacy, tetracycline can be used. A prospective comparison between ceftriaxone and meropenem treatment for 2 weeks followed by trimethoprim-sulfamethoxazole for 1 year showed good 3-year remission in both groups.⁹⁸ However, immune histology still shows some evidence of remaining pathology,⁹⁹ indicating that recurrence could be anticipated after discontinued therapy.

Use of penicillin, streptomycin, and chloramphenicol has been abandoned.⁹⁹

Outcome

Without treatment, Whipple's disease is chronic or relapsing, usually progressive, and ultimately fatal. With adequate antibiotic therapy, clinical remission is usually complete or near complete.

MICROSCOPIC COLITIS

Microscopic colitis (MC) is a name given to two conditions presenting with profuse diarrhea. The first, collagenous

colitis (CC), was described in 1976, and the second, lymphocytic colitis (LC), was published in 1989.¹⁰⁰ They are now joined by a rare third condition called collagenous gastritis (CG).¹⁰¹ Apart from gastrointestinal symptoms, they all may be associated with extraintestinal autoimmune manifestations.

Epidemiology

Although initially considered rare, it is now evident that MC is a common cause of watery diarrhea in several populations. The minimal overall annual incidence is 1 to 5 cases per 100,000. It is 5 to 10 times more common in individuals older than the age of 65 and distinctly more common in women.¹⁰⁰ The female-to-male ratio is 7:1 in collagenous colitis and 2:1 in lymphocytic colitis. The peak incidence is seen among those 60 to 80 years old. For some years the incidence seemed to be increasing, but this has now leveled off.¹⁰²

Cause

The cause is unknown. Although no strong genetic factor has been identified, an association with HLA-DQ2 and with a polymorphism in the *TNF* gene has been described.¹⁰⁰ Exposure to antirheumatic therapy has been suspected in MC patients with rheumatoid arthritis on the basis of the observation that arthritis usually precedes the onset of CC. Reaction against some luminal factor is deduced from the observation that histology is normalized when ileostomy is performed but recurs after closure. Drugs that are prime suspects include NSAIDs and acetylsalicylic acid, lansoprazole, ranitidine, sertraline, and ticlopidine.¹⁰² CC, LC, and CG all seem to be associated with CeD, autoimmune thyroid disease, and arthritis, but no causal relationship is established.

Pathogenesis

Infection is suspected, but no agent has been identified. Luminal factors are strongly suggested by almost complete histologic normalization after performing ileostomy and recurrence of pathology and symptoms after its closure.¹⁰² Connective tissue growth factor was markedly increased in the subepithelial zone of biopsies from CC patients analyzed by reverse transcription PCR, indicating a pathogenic role for connective tissue growth factor (CTGF).¹⁰³ If confirmed, this may lead to targeted therapy of CC.

Clinical Features

Chronic, intermittent (or sometimes chronic, persistent) painful watery stools, weight loss, and fatigue are the cardinal intestinal symptoms. There is no difference between collagenous and lymphocytic colitis in this regard. The course is acute or chronic but usually benign.

CC and LC are associated with a variety of rheumatic syndromes in 10% to 20% of cases. These include Sjögren's syndrome, nondestructive oligoarthritis, migratory arthralgias, sacroiliitis, and rheumatoid arthritis. A survey of 63 consecutive cases in one Swedish center identified 8 cases of rheumatoid arthritis and 3 cases of AS, clearly

Figure 78-15 Collagenous colitis. Note the intact epithelium and massive subepithelial collagen layer. (Courtesy Dr. Claes Lindström.)

suggesting a correlation between colitis and chronic joint disease.¹⁰²

Diagnosis

The diagnosis can be made only by histology obtained at colonoscopy. Endoscopic examination is essentially normal. Lindström found a characteristic thickening of the collagen layer under the gut epithelium. This layer is normally 3 μm , but in CC, it is more than 10 μm and may reach 50 to 100 μm (Figure 78-15). In addition, one can see inflammation and an increased number of lymphocytes. The histology of LC shows an abundance of epithelial lymphocytes (Figure 78-16). In both conditions, the gut epithelium remains intact, although colonic mucosal tears are occasionally present.

Treatment and Outcome

Nonspecific antidiarrheal therapy with 2 to 16 mg loperamide is often effective. Open studies have indicated efficacy of mesalamine 800 mg three times daily either as

Figure 78-16 Lymphocytic colitis. Note the epithelial lesions with intraepithelial lymphocytosis and inflammation of the lamina propria. (From Wollheim FA: *Collagenous colitis and rheumatology*, Curr Rheumatol Rep 2:183–184, 2000.)

monotherapy or in combination with cholestyramine 4 g/day. Budesonide 9 mg/day has good immediate effect but gut relapse is common.¹⁰⁰

PONCET'S DISEASE AND BACILLE CALMETTE-GUÉRIN-INDUCED ARTHRITIS

Tuberculous arthritis, or Poncet's disease, is a rare aseptic form of insidious fever, weakness, and arthritis described mostly in young adults suffering from extrapulmonary tuberculosis.¹⁴ It responds slowly to antituberculous therapy, and in the absence of pulmonary changes, the intestine is assumed to be the port of entry. The attenuated *Mycobacterium* strain bacille Calmette-Guérin (BCG) is used intradermally as an adjuvant in cancer therapy to stimulate T cell-mediated immunity; it is also instilled into the urinary bladder to treat superficial cancer.

Epidemiology

No epidemiologic data are available. A recent review identified 50 bona fide cases of Poncet's disease.¹⁰⁴ Aseptic arthritis occurs in 0.4% to 0.8% of patients treated with the instillation of BCG for bladder malignancy,⁶ and anecdotal evidence indicates an increased prevalence of HLA-B27 among them.¹⁰⁵ This finding was associated with sacroiliitis in 20% and oligoarthritis with predominant localization to the lower limbs; it occurred more often in men. In cases of reactive arthritis occurring after the intradermal administration of BCG, 6 of 10 patients were women and symmetric hand arthritis dominated. In view of the global increase of tuberculosis incidence, one should exercise vigilance regarding possible new cases of Poncet's arthritis.

Cause and Pathogenesis

An aseptic complication of active tuberculosis or the administration of BCG precipitates the process. By definition, it is a reactive arthritis, which means that the infectious agent triggers an immune reaction; however, the enteropathic nature is not firmly established. HLA-B27 may be a susceptibility factor in post-BCG arthritis.⁶

Mycobacterium heat shock protein 65 has been incriminated in both these sterile forms of arthritis, as well as in others.¹⁰⁶ Mycobacterial and human heat shock proteins are 50% homologous, and one hypothesis is that both the therapeutic efficacy and the arthritis are caused by cross-reactive T lymphocytes. Heat shock protein also has homologies with proteoglycan and HLA-DR. The pathogenesis of arthritis after intravesical instillation of BCG might be different and related to antigen persistence, setting the stage for a kind of reactive arthritis.

Clinical Features and Diagnosis

Insidious fever, weakness, and arthritis are described mostly in young adults suffering from extrapulmonary tuberculosis.⁶ The arthritis consists of oligoarthritis or polyarthritis of large or small joints, or both. The onset is not as acute as

in regular enteric reactive arthritis. Most peripheral joints can be affected.⁶ An interesting case was identified in Finland with the help of a sensitive ELISPOT IFN- γ release test. The patient was a female 55-year-old hospital attendant presenting migratory arthritides of an ankle and toes.¹⁰⁷

Arthritis developing in the presence of active tuberculosis or after recent exposure to BCG and proven to be aseptic is sufficient for diagnosis.

Treatment and Outcome

There is no established treatment. Post-BCG cases usually heal within 3 months. However, despite negative culture results, 4 to 6 months of conventional antituberculous therapy is often practiced.¹⁰⁷

ENTEROVIRAL AND HEPATITIS VIRUS-ASSOCIATED ARTHRITIS

Epidemiology

Enterovirus infections, like other common virus infections, often give rise to arthralgias. The precise prevalence is not known. Hepatitis B and hepatitis C disease cause joint manifestations in 10% to 25% of cases.

Genetics and Pathogenesis

No genetic factors have been identified. *Enterovirus* species can invade joints and may rarely be isolated from joint fluid.¹⁰⁸ Immune complex-mediated activation may result in viral hepatitis. A preferential deposition of such immune complexes in joints results in arthralgias and arthritis.¹⁰⁹ In hepatitis C disease, precipitation of cryoglobulins is often observed. Molecular mimicry has been proposed but not proved.¹¹⁰ Viral persistence in host cells with continuous production of viral protein expressed on cell surfaces has been observed.¹¹¹ Immunosuppressive therapy may reactivate latent virus growth and may be misinterpreted as increased disease activity in patients with other rheumatologic conditions.

Clinical Features

Hepatitis B may be associated with a variety of general symptoms including fever, abdominal pain, nausea, and vomiting after a prodromal period of up to 6 months. Among these patients, 10% to 25% also develop articular symptoms, which may present during the prodromal phase. Preferentially, locations are hands and knees. In addition to morning stiffness, migratory arthritis is common. Interestingly, a coincident appearance of urticaria-like rash, predominantly of the legs, is common. The arthritis characteristically disappears with the onset of jaundice.¹¹²⁻¹¹⁴

Less than 5% of hepatitis B-infected individuals develop a chronic disease with persistent or remitting articular manifestations. The disease is self-limited and only requires symptomatic treatment.^{110,115}

Hepatitis C virus is associated with joint symptoms in 20% of cases. Other frequent symptoms are myalgia, glomerulonephritis, and vasculitis or essential mixed

cryoglobulinemia, which may become severe. Oligoarthritis occurs in one-third of the cases, whereas two-thirds develop polyarticular disease.^{109,116}

Enteroviruses, coxsackieviruses, and echoviruses are only associated with arthropathy in less than 1% of cases, but due to the high prevalence of the primary disease the number of arthritis cases is not trivial.¹¹⁶⁻¹¹⁸ After an incubation period of 3 to 5 days the patients develop fever, fatigue, headache, pharyngitis, myalgia, rash, pleuritic pain, and conjunctivitis or, alternatively, nausea, abdominal pain, enteric cramps, vomiting, and diarrhea. Joint symptoms are self-limited and disappear within days, although recurrence can occur. Any peripheral joint may be affected.¹¹⁹

Etiology and Pathogenesis of Systemic Lupus Erythematosus

MARY K. CROW

KEY POINTS

Systemic lupus erythematosus (SLE) results from chronic and recurrent activation of the immune system, with production of antibodies and other protein products contributing to inflammation and tissue damage.

SLE is a disease with typical onset in the childbearing years and most common in females, suggesting a role for both hormones and as yet uncharacterized sex-related factors in disease pathogenesis.

Progress in genetic analysis has resulted in identification of genetic variants associated with SLE, with most related to innate and adaptive immune system function. Complement deficiencies confer the highest risk of disease, and mutations in *TREX1* point to impaired regulation of endogenous nucleic acids as an important pathogenic mechanism.

Environmental factors contribute to initiation of lupus and lupus flares.

The discovery of the Toll-like receptor family of innate immune receptors has led to important advances that point to a significant role for innate immune system activation in SLE pathogenesis.

A contribution of nucleic acid-containing immune complexes as stimuli for endosomal Toll-like receptors has added an important new role for immune complexes in the pathogenesis of SLE.

Production of type I interferon (IFN), broad expression of type I IFN-inducible genes, and the effects of IFN on immune system activation and function have emerged as central mechanisms of lupus pathogenesis.

Impaired regulation of the adaptive immune response contributes to autoantibody production and has informed development of new therapies.

Platelets and neutrophils, along with neutrophil extracellular material, have gained new attention as important pathogenic effectors. Complement remains an important mediator of inflammation.

the potential to cause significant physical disfigurement, morbidity, and occasionally mortality, lupus is the focus of strong advocacy to support research that will generate insights into disease pathogenesis. In fact, characterization of the immunologic contributors to lupus, the prototype systemic autoimmune disease, has been the focus of particularly intense study since the flowering of the discipline of immunology in the 1950s and 1960s. Recent efforts to define the genetic variations that underlie susceptibility to lupus have supported the central role of the immune system in disease pathogenesis but have extended the view of lupus pathology beyond the important role of autoantibodies to include a significant contribution of the innate immune system to disease. An underlying role for the vasculature as a target of the immune system and its products is gaining renewed interest as an important component of lupus pathogenesis. Together, these recent advances provide important insights into how the intersection of genetic variations with environmental triggers amplifies immune system activation and target organ vulnerability to generate the classic manifestations of lupus and its clinically significant comorbidities. [Figure 79-1](#) provides a schematic overview of many of the contributors to SLE and how they interact to drive autoimmunity and tissue damage.

HISTORICAL VIEW OF LUPUS PATHOGENESIS

Insights into the immunopathogenic mechanisms that account for development of autoimmunity in patients with SLE and the tissue damage that results in disease have come in fits and starts over many decades. Progress has been informed by the scientific tools available at the time along with the acute observations of clinicians and research scientists. Descriptions of the clinical manifestations of disease suggested a multisystem disease that typically involves skin and joints, with renal, cardiac, and neurologic pathology suspected and then documented once histologic studies were performed. Alterations of blood vessels in many organs were recognized as an important component of the disease process in early studies, with the pathognomonic “onion

Systemic lupus erythematosus (SLE) represents one of the most significant diseases in all of medicine. Predominantly targeting young women in their childbearing years and with

Figure 79-1 Contributors to systemic lupus erythematosus (SLE) pathogenesis. Mechanisms that promote development of SLE are related to the underlying genetic profile of the individual. Many of the disease-associated genetic variants (examples are illustrated) contribute to excessive production or impaired clearance of stimulatory nucleic acids; increased generation of products of the innate immune response, particularly type I interferon (IFN); or an altered threshold for activation or efficiency of signaling of cells of the adaptive immune response. In most cases multiple genetic risk variants are required to establish a state of immune activation that is receptive to environmental triggers that promote development of autoimmunity. In rare cases, a mutation of a critical regulator of immune activation might be sufficient to initiate the altered immune state that can lead to disease. Type I interferon is a product of plasmacytoid dendritic cells (pDCs), and activation of those cells by intracellular nucleic acids or exogenous triggers such as a virus or debris derived from damaged or dying cells might represent mechanisms of initiation of disease. Once IFN- α is produced, it mediates numerous effects on immune system cells that mimic the response to a viral infection. The antigen-presenting capacity of myeloid dendritic cells can be augmented, promoting activation of self-reactive T cells and differentiation of B cells toward production of pathogenic antibodies. Activated T cells express CD154 (CD40 ligand) and produce interleukin-21 (IL-21), providing effective help for B cells to generate antibody-producing plasma cells. IFN- α also supports the production of B cell activating factor (BAFF), a survival and differentiation factor for B cells. Once autoantibodies are produced, immune complexes amplify immune activation by accessing endosomal Toll-like receptors in pDCs and B cells and deposit directly in the vicinity of blood vessels, inducing complement activation, inflammation, and tissue damage. Reactive oxygen species (ROS) and proinflammatory cytokines produced by monocytes and macrophages contribute to tissue damage, as does IFN- α , which stimulates endothelial cells and is associated with poor vascular repair and sclerosis. BCR, B cell receptor; DC, dendritic cell; MHC, major histocompatibility complex; M ϕ , macrophage; PMN, polymorphonuclear neutrophil; RNA, ribonucleic acid; TCR, T cell receptor.

skinning" of splenic arterioles, cellular infiltration and damage to renal glomeruli, and vasculopathy in skin and brain demonstrated clinically by manifestations such as nephritis, livedo reticularis, and stroke. The lupus erythematosus (LE) cell, described by Hargraves in 1948, suggested that engulfment of cellular debris, a mechanism that remains an important concept in considerations of lupus pathogenesis, was active at sites of inflammation.

The recognition that antibodies directed at cellular components, particularly cell nuclei, were present in the sera of patients with SLE directed the attention of the investigator community toward the immune system and the conclusion

that lupus reflected an autoimmune process. Together with pathologic studies of kidneys from lupus nephritis that showed deposition of immunoglobulin and complement components in kidney glomeruli, the elution of anti-deoxyribonucleic acid (DNA) autoantibodies from lupus kidneys contributed to the concept that autoantibodies, particularly anti-DNA antibodies, were pathogenic. Isolation from lupus sera of complexes of antibody with DNA or DNA-binding proteins such as histones was an important factor in classifying SLE as predominantly an immune complex-mediated autoimmune disease. Although lupus pathogenesis does depend on those immune complexes and

the inflammatory responses that they induce, subsequent investigation identified virtually all cell components and many soluble immune system products as contributors to the immune system dysfunction that ultimately accounts for disease in SLE.

The development of the field of cellular immunology in the 1970s and the later identification of the T cell antigen receptor, along with families of co-stimulatory molecules mediating interactions between T cells and antigen-presenting cells or B cells, led to the implication of self-reactive T cells as important regulators of immune responses, as well as helpers for B cell differentiation to autoantibody-producing cells in the case of patients with SLE. Numerous deficiencies in T cell function including altered production of typical T cell cytokines such as interleukin-2 (IL-2) were described, and studies of murine lupus models strongly supported the essential role that T cells play in lupus pathogenesis.

The discovery of Toll-like receptors (TLR) in the 1990s, the recognition that those receptors recognize common determinants expressed by microbes, and the demonstration that TLRs mediate immune system activation was a major advance, perhaps the most significant milestone in many decades, that has led to gains in understanding of lupus pathogenesis. Characterization of the typical exogenous ligands of each of the TLRs has been followed by identification of endogenous ligands for their receptors, with nucleic acids being the most relevant for amplification of immune system activation and autoimmunity in SLE. It is not yet clear if the TLRs act to augment immunologic activity that is initiated by other molecular pathways or if they are also essential as sensors for the primary initiators of autoimmune disease.

In spite of these considerable gains in elucidating the pathogenesis of SLE, the environmental triggers and genetic susceptibility factors that lead to the initiation of autoimmunity in some individuals but not in others remain largely undefined. Regarding triggers of disease, clinical observations have pointed to exposure to sunlight, microbial infection, and certain drugs as factors that can lead to initiation or exacerbation of lupus. Whether there is a common thread among these environmental triggers is not clear, but ultraviolet light-mediated DNA damage and modification of DNA methylation are among the processes that might render self-nucleic acid stimulatory to the immune system.

Significant technologic advances in recent years, together with development of consortia of investigators who have cooperated to share biologic samples from patient cohorts and control subjects, have supported important progress in defining the genetic variants that show a statistical association with a diagnosis of SLE. These recent genome-wide association studies (GWASs) have built on long-standing observations of the high risk of disease in patients with complement deficiencies to identify lupus-associated genes that encode important components of molecular pathways that promote production of type I interferon (IFN), alter the threshold for activation of lymphocytes, or generate immune stimuli.

Together, these scientific advances have led to the recent, long-awaited activity in drug development programs targeting mechanisms likely to impact lupus disease activity or

clinical progression. This chapter reviews those recent studies that have illuminated the immunopathogenesis of SLE.

GENETIC CONTRIBUTIONS TO LUPUS PATHOGENESIS

Current concepts in genetic studies of complex human diseases including SLE identify both common variants with a small impact on risk of disease, as well as low-frequency mutations that can have a great impact on the risk of developing lupus or a lupus-like syndrome.

Observations of several individuals with SLE within a family, along with a high frequency of concordance of SLE in identical twins, have pointed to a strong genetic contribution to SLE. Data suggest that concordance of clinical lupus disease in twins is 10 times more frequent in monozygotic than in dizygotic twins, although the highest reported concordance rate is still only 57%. Moreover, the suggestion that multiple autoimmune diseases are associated with common genetic susceptibility factors is supported by the aggregation of several distinct autoimmune diseases within a family. The pace of discovery of common genetic variants, typically identified by statistical analysis of single nucleotide polymorphisms (SNPs) in relation to a diagnosis of SLE, has markedly accelerated in recent years, as the cost of genotyping thousands of patient and control samples has become feasible. Publication of two important collaborative genome-wide association studies, one by the SLE Genetics (SLEGEN) consortium and the other organized by Genentech, identified at least nine new genes or genomic loci associated with SLE.^{1,2} Since presentation of those studies, additional lupus-associated genetic variants have been confirmed or at least strongly supported.³ The common theme among the lupus-associated genes is that the vast majority encode proteins implicated in immune system function. Although this result is not surprising, it confirms the essential contribution of the immune system to the autoimmunity, inflammation, and tissue damage that characterize lupus disease and points to the most significant molecular pathways that mediate altered immune function.

The lupus-associated genes that play likely roles in lupus pathogenesis can be grouped on the basis of their roles in immune function (Table 79-1). In parallel to the requirements for immune system activation stimulated by foreign antigens, SLE-associated genes are involved in generation of self-antigen, activation of the innate immune response, and activation of the adaptive immune response. Although the specific functional alterations that are conferred by the lupus-associated variant compared with the more common variant have yet to be defined in detail, in most cases there is sufficient information regarding function to allow formulation of hypotheses that can be tested in functional genetic studies.

The rare but high-risk deficiencies in complement pathway gene products, including C2, C4, and C1q, are thought to contribute to lupus pathogenesis by impairing clearance of cellular debris, a function that is typically supported by those complement components. Increased availability of nuclear debris can provide sufficient self-antigen for induction of self-reactive T cells or serve as an

Table 79-1 Genetic Variants Associated with Systemic Lupus Erythematosus (SLE)

Major Histocompatibility Complex (MHC) Genes Associated with SLE
Homozygous deficiencies of early complement components (C2, C4A, C4B) (increase risk 5- to 10-fold)
<i>HLA-DR2</i> (increases relative risk twofold to threefold)
<i>HLA-DR3</i> (increases relative risk twofold to threefold)
<i>DR2/DRX</i> associated with anti-Sm antibodies
<i>DR3/DRX</i> associated with anti-Ro and anti-La antibodies
<i>DR2/DR3</i> associated with anti-Ro, anti-La, and/or anti-Sm and also associated with anti-dsDNA antibodies
<i>DR3/DR3</i> associated with anti-Sm antibodies
Non-MHC Genes Associated with SLE
Homozygous deficiency of C1q (increases risk 5- to 10-fold)
Associations Based on Linkage Studies
Fc gamma receptor IIa (<i>FCGR2A</i>)
Fc gamma receptor IIIa (<i>FCGR3A</i>)
Programmed cell death 1 (<i>PDCD1</i>)
Associations Based on Candidate Gene Studies
C-reactive protein (<i>CRP</i>)
Interferon regulatory factor 5 (<i>IRF5</i>) (supported by GWAS)
Interleukin-10 (<i>IL-10</i>)
Protein tyrosine phosphatase 22 (<i>PTPN22</i>) (supported by GWAS)
Associations Based on or Confirmed by Genome-Wide Association Studies
B cell scaffold protein with ankyrin repeats (<i>BANK1</i>)
B lymphocyte specific tyrosine kinase (<i>BLK</i>)
V-ETS avian erythroblastosis virus E26 oncogene homolog 1 (<i>ETS1</i>)
Ubiquitin-conjugating enzyme E2L (<i>UBE2L3</i>)
Ikaros family zinc finger 1 (<i>IKZF1</i>)
Interleukin-1 receptor associated kinase/methyl-CpG-binding protein 2 (<i>IRAK1/MECP2</i>)
Integrin α M (<i>ITGAM</i>)
Juxtaposed with another zinc finger gene (<i>JAZF1</i>)
PHD and ring finger domains 1 (<i>KIAA1542/PHRF1</i>)
WD repeat- and FYVE domain-containing protein 4 (<i>WDFY4</i>)
V-yes Yamaguchi sarcoma viral related oncogene homolog (<i>LYN</i>)
Nicotinamide nucleotide adenylyltransferase 2 (<i>NMNAT2</i>)
PR domain-containing protein 1 (<i>BLIMP1</i>) (<i>PRDM1</i>)
PXK domain-containing serine/threonine kinase (<i>PXK</i>)
RAS guanyl nucleotide-releasing protein 3 (<i>RASGRP3</i>)
Solute carrier family 15, member 4 (<i>SLC15A4</i>)
Signal transducer and activator of transcription 4 (<i>STAT4</i>)
Tumor necrosis factor–induced protein 3 (<i>TNFAIP3</i>)
Tumor necrosis factor ligand superfamily, member 4 (<i>OX40L</i>) (<i>TNFSF4</i>)
<i>TNFAIP3</i> -interacting protein 1 (<i>TNIP1</i>)
3-prime repair exonuclease 1 (<i>TREX1</i>)
XK, Kell blood group complex subunit-related family, member 6 (<i>XKR6</i>)
Rare Genetic Mutations Associated with Lupus
3-prime repair exonuclease 1 (<i>TREX1</i>)
Ribonuclease H2, subunit A-C (<i>RNASEH2A-C</i>)
SAM domain- and HD domain-containing protein 1 (<i>SAMHD1</i>)

GWAS, genome-wide association study.

endogenous adjuvant for activation of the innate immune response. The ancestral major histocompatibility complex (MHC) 8.1 haplotype block, HLA-B8/DR3/DQw2/C4A_{QO}, that is associated with lupus susceptibility, encodes the alleles B8 and DR3 and bears a short C4B gene and no C4A gene, whereas other nonrisk haplotypes carry either a longer C4B segment and/or one or more copies of C4A. In fact, the relative risk related to the C4A null allele

is twice that of either HLA-B8 or DR3, pointing to the significance of the C4 genes in disease risk.⁴ It should be noted that this risk haplotype is also associated with accelerated disease in patients infected with human immunodeficiency virus (HIV), insulin-dependent diabetes mellitus, and several other autoimmune diseases. Deficiency of C1q, the recognition protein for the classical complement pathway, might contribute to disease on the basis of its important role in promoting clearance of apoptotic cell debris by mononuclear phagocytes.⁵ C1q plays an additional role in inhibition of IFN- α production by directing stimulatory immune complexes to monocytes rather than IFN-producing plasmacytoid dendritic cells. Through this mechanism C1q deficiency can augment IFN- α and promote broad immune dysregulation.⁶ C-reactive protein (CRP), a member of the pentraxin family, also contributes to clearance of apoptotic debris. Polymorphisms in *CRP* have been associated with SLE and with decreased levels of CRP, but it remains unclear how much of the genetic contribution to basal CRP levels is due to variations within the gene itself versus variations in other genes.

Recent studies of families with a lupus-like disease, the Aicardi-Goutières syndrome, suggest that mutations in genes encoding nucleases that cleave either DNA or ribonucleic acid (RNA) might result in excess stimulatory nucleic acid and innate immune system activation.^{7,8} Aicardi-Goutières and several related conditions are characterized by skin lesions, autoantibodies, central nervous system disease, and high levels of type I IFN. Mutations in the *TREX1* gene, encoding DNase III, a 3'-5' exonuclease, as well as two additional genes, *RNASEH2* and *SAMHD1*, are associated with this syndrome.⁹ A functional connection between *TREX1* and control of type I IFN production was demonstrated in a murine model in which *TREX1* deficiency resulted in increased levels of IFN- β .¹⁰ A recent analysis of more than 8000 lupus patients found *TREX1* mutations in approximately 0.5% of patients. In addition, a common variant in the *TREX1* gene conferred an odds ratio for diagnosis of lupus of 1.73 compared with healthy controls.¹¹ Taken together, these recent demonstrations of association of rare genetic variants of enzymes that regulate degradation of nucleic acids with SLE point to the central role of those nucleic acids as triggers for immune system activation and disease.

A large number of lupus-associated single nucleotide polymorphisms (SNPs) are found in genes that encode proteins involved in induction of type I IFN or response to that family of cytokines.¹²⁻¹⁴ IFN regulatory factor 5 (*IRF5*) and *IRF7* are cytoplasmic proteins that translocate to the nucleus after effective activation of the endosomal TLRs by DNA or RNA. *IRF5* and *IRF7* then act as transcription factors to initiate transcription of IFN- α and other proinflammatory mediators. *TNFAIP3* encodes A20, a protein that regulates several proinflammatory cellular mechanisms including signaling through endosomal TLRs and activation of nuclear factor κ B (NF κ B).¹⁵ Genetic variants in *IRF5*, *IRF7*, *TNFAIP3*, and numerous other lupus-associated genetic variants can be mapped to molecular pathways responsible for induction of innate immune system activation or responsiveness to its products, particularly IFN- α .

A third set of lupus-associated gene variants contributes to altered thresholds for lymphocyte activation or efficiency

of cell activation. The ancestral MHC 8.1 haplotype that has been shown to be strongly associated with a diagnosis of SLE, along with other autoimmune diseases, appears to influence the early stages of immune system activation. Although more efficient presentation of self-antigens by disease-associated MHC class II alleles would seem to be the most likely mechanism by which the MHC risk haplotype confers predisposition to autoimmunity, available data point to a number of immune alterations, many focused on the T cell, in healthy individuals bearing the ancestral haplotype.⁴ The impact of those alleles is best defined clinically as determining immune responses that generate particular autoantibody specificities, and the alleles seem to be important in determining whether anti-DNA autoantibodies, antibodies specific for RNA-associated proteins, or both types of autoantibodies can be induced and produced through T cell–dependent B cell differentiation.¹⁶ Additional lupus-associated variants that alter adaptive immune system activation are involved in cytokine signaling such as *STAT4* or efficiency of signaling downstream of the T and B cell surface antigen receptors such as *PTPN22* in the case of both T and B cells and *LYN*, *BANK*, *BLK*, *TNFAIP3*, and others in the case of B cells.

A fourth category of lupus-associated genetic variants defines determinants of target organ damage. The understanding of genetic determinants of target organ vulnerability to immune mediated or oxidative damage is less well developed than is the role of genetic variants in altered immune system function in SLE, but identification of polymorphisms in members of the kallikrein gene family are associated with SLE and suggest areas for future investigation.¹⁷ Table 79-1 lists many of the genetic variants documented to have a statistical association with a diagnosis of SLE.

Although impressive progress based on GWAS has identified statistical association of sequence variations in genes or genetic loci with a diagnosis of SLE, the functional consequences of those variations have not been extensively characterized. The best developed insights regarding the impact of lupus-associated variants on immune function have derived from studies of gene products involved in production of type I IFN. The risk alleles for *IRF5* and *IRF7* are associated with increased serum type I IFN activity in those patients who demonstrate autoantibodies targeting DNA or RNA-associated proteins.^{12,18} Those studies support the hypothesis that nucleic acid–containing immune complexes are important stimuli that act through endosomal TLRs such as TLR7 and TLR9, those TLRs that mediate cell signals through the IRF5 and IRF7 transcription factors.

The impressive collaborative efforts that have successfully collected sufficient patient and control samples and performed the required genotyping and statistical analyses have defined or at least confirmed those molecular pathways that are central to the immunopathogenesis of SLE. The strong support for activation and altered regulation of the TLR pathway, along with variations in lymphocyte signaling, point to potential therapeutic targets for future study. In addition, the recent identification of less common mutations in enzymes required for degradation of intracellular nucleic acids suggests that further study of the TLR-independent pathways of innate immune system activation, mediated by nucleic acid sensors and their associated kinases

and adaptor molecules, might be another fruitful area for further investigation.

Subphenotype analysis will continue to amplify the information that can be gleaned from patient and control genotyping. A recent study of anti-dsDNA⁺ and anti-dsDNA[−] SLE patients, along with healthy controls, identified HLA-DR3, *STAT4*, and *ITGAM* as significantly associated with the presence of anti-dsDNA antibodies.¹⁹ A case-only analysis additionally associated *PTPN22*, *IRF5*, and *PTTG1* with anti-dsDNA antibodies. In contrast, a distinct group of lupus-associated genes showed comparable association between anti-dsDNA positive and negative patients, including *FCGR2A*, *OX40L*, *IL10*, *PXK*, *UHRF1BP1*, *PRDM1*, *BLK*, and *IRAK1*. Although it is possible that some of these variants are associated with distinct autoantibody specificities, it is more likely that they represent risks for other aspects of lupus pathogenesis, perhaps contributing to inflammation and tissue damage.

Whether the insights regarding specific genetic susceptibility factors can be used to predict development of lupus or particular manifestations of disease is as yet unclear. Recent studies have attempted to determine the predictive value of accumulated genetic risk variants. Although increased numbers of lupus-associated alleles are associated with some increased risk of disease and the number of lupus-associated genetic alleles is significantly higher in patients with anti-dsDNA antibodies than in those without those autoantibodies, at this time, it would not appear that genotyping for lupus risk is sufficiently informative to warrant practical application in patient management.²⁰

FEMALE PREDOMINANCE OF SYSTEMIC LUPUS ERYTHEMATOSUS

A discussion of genetic contributions to SLE pathogenesis cannot ignore the dramatic 9:1 female predominance of the disease. Of all of the characteristic clinical features of lupus, it is the extreme sex skewing that remains least understood. Hormonal contributions to immune system activation are likely to represent a component of the female predominance of the disease; estrogen can modulate lymphocyte activation, and prolactin has been shown to be expressed at increased levels in lupus serum.²¹

Granting a contribution of hormones to increased immune activation, it would appear that additional concepts should be entertained to understand why 9 or 10 females are diagnosed with SLE for every male lupus patient. It is intriguing that Klinefelter's syndrome, characterized by a 47,XXY genotype, is increased 14-fold among men with SLE compared with men without SLE.²² These data are proposed to support an X chromosome gene dose effect as an important contributor to SLE pathogenesis. Identifying the X chromosome as a possible risk factor for SLE provides a basis for new hypotheses regarding disease susceptibility, but the nature of that risk remains undefined. A possible role for altered regulation of epigenetic processes such as DNA methylation has been raised, and murine studies have supported the impact of duplications of portions of the X chromosome that encode the *TLR7* gene in activation of the innate immune system, production of type I IFN, and generation of autoimmunity.²³ Investigation of

altered gene dosage in human patients has not confirmed a similar duplication of the *TLR7* gene, and studies of DNA methylation are most suggestive of altered DNA methylation reflecting generalized immune activation rather than a primary etiologic event.²⁴ Further studies of epigenetic regulation of X chromosome structure and gene expression are warranted.

A potential pathogenic role for the distinct events that occur in the ovary compared with those in the testes also deserves further study. Onset of SLE most typically occurs in the childbearing years, after menarche and before menopause. A positive association between early menarche and SLE has been observed, and breastfeeding confers a protective effect.²⁵ Both observations might be consistent with molecular and cellular events related to ovulation as factors contributing to lupus pathogenesis. It is intriguing to consider that the biology of germ cell maturation, with female germ cells undergoing a second meiotic division before ovulation each month, might involve mechanisms and mediators that affect immune recognition. Although not yet fully understood, the carefully orchestrated demethylation and remethylation of DNA, along with the production of regulatory RNAs and RNA-associated proteins such as so-called PIWI proteins, in the germ cells and associated somatic cells might provide a source of stimulatory nucleic acid-containing complexes that could access TLR-dependent or TLR-independent pathways and result in immune activation.²⁶ The challenge in pursuing such concepts is the obvious limitation on access to ovarian tissue for study, although murine models might be helpful in that regard.

ENVIRONMENTAL TRIGGERS OF LUPUS

Concordance rates for development of SLE in identical twins range from 24% to 57%, and it is understood that both environmental factors and stochastic events (i.e., chance) contribute to development of SLE in an individual. Although some environmental triggers of disease have been identified on the basis of clinical observation and epidemiologic studies (Table 79-2), in general there is incomplete understanding of the range of factors that can induce disease and the mechanisms by which they do so. Socioeconomic factors have been demonstrated to contribute to poor outcomes in lupus patients, likely related to poor access to care.²⁷ The distinct contributions of low socioeconomic status versus genetic factors that impact disease severity in certain ethnic groups are difficult to dissect.

Clinical manifestations that are often present at the time of diagnosis including fatigue and arthralgias have suggested that a virus might initiate the disease. In fact, epidemiologic studies demonstrating higher prevalence of antibodies specific for Epstein-Barr virus (EBV) antigen in children with SLE compared with the general population, as well as higher frequency of anti-EBV antibodies in a military cohort before diagnosis of lupus, support a possible role for that virus in disease pathogenesis.²⁸ In addition, SLE patients demonstrate increased EBV DNA in blood.

Several potential mechanisms might account for a pathogenic role for EBV in SLE including production of EBV-encoded RNAs that induce type I IFN, utilization of B cell signaling pathways to promote B cell activation and differentiation, and generation of autoantibodies reactive

Table 79-2 Environmental Factors That Might Play a Role in the Pathogenesis of Systemic Lupus Erythematosus (SLE)

Definite
Ultraviolet B light
Probable
Estrogen and prolactin—in humans, female-to-male ratio is 9:1 between menarche and menopause, 3:1 in young and old
EBV
Lupus-inducing medications*
Hydralazine
Procainamide
Isoniazid
Hydantoins
Chlorpromazine
Methyldopa
Penicillamine
Minocycline
Tumor necrosis factor inhibitors
Interferon- α
Possible
Dietary factors
Alfalfa sprouts and related sprouting foods containing canavanine
Pristane and other hydrocarbons
Infectious agents other than EBV
Bacterial DNA
Smoking
Human retroviruses or endogenous retroelements
Endotoxins, bacterial lipopolysaccharides
Vitamin D deficiency

*Although each drug listed and many others can induce lupus-like symptoms in predisposed individuals, there is little evidence that they can induce true SLE or even activate disease in individuals with spontaneous, established SLE. If the clinical care of a patient with SLE would benefit from the use of one of these drugs, the drug should not be withheld.

DNA, deoxyribonucleic acid; EBV, Epstein-Barr virus.

with DNA or RNA-binding proteins through a molecular mimicry mechanism.²⁹ EBV-encoded small RNAs or EBERs are expressed in cells latently infected with EBV. EBERs induce expression of type I IFN after binding to the dsRNA-dependent protein kinase (PKR) and activating signaling through a TLR-independent pathway. Latent membrane protein 1, encoded by EBV, can act as a mimic of CD40 and promote B cell dysfunction and autoimmunity in lupus-susceptible mice.³⁰ A recent study demonstrates that antibodies specific for the virus-encoded EBNA-1 protein can also react with dsDNA.³¹ The molecular basis of this apparent cross-reactivity is not known, although DNA can associate with EBNA-1 and might account for the described antibody reactivity. T cell responses specific for EBV have been studied in patients with lupus and found to be deficient, perhaps contributing to the increased numbers of EBV-infected mononuclear cells and increased copy number of EBV DNA found in SLE patients.³²

Environmental toxins are of interest, yet their potential role in lupus pathogenesis has not been comprehensively explored. Data support current smoking as a risk factor for SLE, with a dose response relating pack years of smoking to risk. As is currently proposed with regard to pathogenesis of rheumatoid arthritis, smoking might provide an inflammatory stimulus to epithelial or mononuclear cells in the lungs, promoting protein modification or nonspecific

inflammation. Silica has also been proposed as a potential pathogenic factor in SLE on the basis of its known capacity to serve as an adjuvant.³³

Two well-described triggers of lupus, ultraviolet light and certain drugs, are likely to promote lupus pathogenesis through their effects on DNA. Ultraviolet (UV) light has many effects on skin cells including induction of DNA breaks that might alter gene expression or lead to apoptotic or necrotic cell death. Even in the absence of cell death, DNA breaks or prolonged maintenance of DNA-protein cross-links might provide either an adjuvant or antigenic stimulus to the immune system. Altered DNA methylation has been proposed as a likely mechanism of drug-induced lupus.³⁴ In the case of hydralazine, the drug inhibits extracellular signal-regulated kinase (ERK) pathway signaling, resulting in decreased expression of DNA methyltransferase 1 (DNMT1) and DNMT3a, two enzymes that mediate DNA methylation. Altered DNA methylation modifies gene expression and might also expose potential ligands for TLR-mediated immune system activation.

INNATE IMMUNE SYSTEM ACTIVATION IN SYSTEMIC LUPUS ERYTHEMATOSUS

Arguably the most significant recent advance that has improved understanding of the pathogenesis of SLE and other autoimmune and inflammatory diseases is the discovery of the TLRs and, more generally, the elucidation of the central role of innate immune system activation in regulation of the adaptive immune response, inflammation, and tissue repair. The TLRs are composed of an ectodomain with leucine-rich repeats, a transmembrane domain, and a cytoplasmic domain that associates with adaptor molecules that initiate signaling, resulting in activation of members of the IFN-regulatory factor family, NFκB, and members of the MAP kinase family. TLR-independent innate immune activation is initiated by intracytoplasmic nucleic acid sensors such as RIG-I and MDA5, which use distinct adaptors to trigger signal transduction through IRFs and the NFκB pathway. Over the past decade studies of nucleic acid-responsive TLRs and TLR-independent nucleic acid sensors that result in production of type I IFNs and other proinflammatory mediators have identified a direct pathogenic role for nucleic acids and nucleic acid-containing immune complexes as mediators of immune dysfunction in lupus. These studies complement the demonstration of broad expression of type I IFN-inducible genes in peripheral blood cells of lupus patients, referred to as the “IFN signature.”³⁵⁻³⁷ Together, the data point to the innate immune response and its products as significant factors in lupus pathogenesis. Table 79-3 describes many of the key components of the TLR-dependent and TLR-independent immune system pathways that are important in activation and control of lupus immune responses.

The endosomal TLRs, particularly TLR7, reactive with single-stranded RNA, and TLR9, reactive with unmethylated CpG-rich DNA, have been associated with lupus pathogenesis on the basis of in vitro studies that demonstrate activation of those TLRs by immune complexes that gain access to their intracytoplasmic compartment with the help of Fc receptors that bind the Fc fragment of

Table 79-3 Key Components of TLR-dependent and TLR-independent Innate Immune Response Pathways Relevant to the Pathogenesis of SLE

TLR-dependent Pathway
Receptors
Endosomal TLRs (TLR7 and TLR9) TLR4 TLR3?
Adaptors
Myeloid differentiation primary response gene 88 (MyD88) Toll/IL-1 receptor (TIR)-domain-containing adaptor protein (TIRAP) TIR-domain-containing adaptor protein inducing interferon-β (TRIF) TRIF-related adaptor molecule (TRAM) TNF receptor-associated factor 6 (TRAF6)
Kinases
Interleukin-1 receptor associated kinase-1 (IRAK1) IRAK4 Mitogen-activated protein kinase kinase kinase 7 (MAP3K7/TAK1) I-kappa B kinase alpha and beta (IKKα/β) I-kappa B kinase gamma (NEMO)
Transcription Factors

immunoglobulin in the complex.³⁸⁻⁴⁰ Clinical data demonstrating association of autoantibodies with specificity for RNA-binding proteins (such as Ro, La, Sm, and RNP) with high expression of IFN-induced genes in patient peripheral blood cells point to a significant role for RNA-containing

immune complexes in innate immune activation and IFN production.⁴¹ Associated neutrophil-derived proteins including high mobility group box 1 (HMGB1) and the cathelicidin protein LL37 can facilitate access of those immune complexes to the TLR-containing endosome. Lupus mice made deficient in one or another TLR have supported the role of TLR7 in generating type I IFN, autoantibodies specific for RNA-binding proteins and disease.⁴² TLR9 activation can also generate IFN- α , but the findings from TLR9-deficient MRL/lpr mice have been somewhat confusing because those mice show more severe disease, suggesting that the activation of TLR9 might actually be protective. It appears that TLR9 activation can regulate the TLR7 pathway, resulting in reduced production of RNA-related autoantibodies.⁴³ In addition to demonstrating

the important role of the endosomal TLRs in lupus pathogenesis, the data link TLR pathway activation with production of particular autoantibody specificities. These significant advances in characterization of the role of TLRs and the innate immune response in lupus disease have suggested new therapeutic approaches that are currently being pursued (Figure 79-2).

The elucidation of the mechanisms of induction of type I IFN, with plasmacytoid dendritic cells (pDCs) the major producers, have promoted studies that identified roles for additional cell types in amplification of this pathway. Platelets, largely ignored in studies of SLE pathogenesis, were shown to promote IFN production by pDCs through signals mediated by CD40 ligand (CD154) on activated platelets and CD40 on the pDCs.⁴⁴ One of the

Figure 79-2 Endogenous stimuli for innate immune system activation. Endogenous molecules released by dying cells such as high mobility group box 1 (HMGB1) and β -defensins are recognized by cell surface Toll-like receptors (TLRs) and induce production of inflammatory mediators. Self-DNA or self-RNA, either in association with HMGB1 or LL37 or in the form of immune complexes that bind Fc receptors, is internalized into endosomal TLRs and transducer signals that result in transcription of type I interferon or proinflammatory cytokines. Self-nucleic acids can also be recognized by cytoplasmic sensors and trigger gene expression that contributes to immune activation, autoimmunity, and inflammation. DNA, deoxyribonucleic acid; ECM, extracellular matrix; Hsp, heat shock protein; LDL, low-density lipoprotein; RAGE, receptor for advanced glycation end products; RNA, ribonucleic acid; TBK1, TANK-binding kinase 1. (From Kawai T, Akira S: *The role of pattern-recognition receptors in innate immunity: update on Toll-like receptors*, Nat Immunol 11:373–384, 2010.)

initial microarray data sets demonstrating an IFN gene expression signature in peripheral blood cells of pediatric lupus patients also detected expression of genes that are typically expressed in granulocytes.³⁵ Recent studies from several groups have extended this observation and have documented low-density granulocytes in the circulation of lupus patients.⁴⁵

Neutrophil extracellular traps (NETs) have gained attention as potential mediators of innate immune system activation. The NETs derive from a discrete cellular process, termed *NETosis*, in which aggregates of chromatin including DNA and its associated histones, HMGB1, LL37, elastase, and myeloperoxidase, are systematically extruded from nuclei into the extracellular environment. Generation of the NETs can be induced by interaction of neutrophils with vascular endothelial cells, activated platelets, or various cytokines. Recent data also implicate nucleosomes and RNA-containing immune complexes in the induction of NETosis.⁴⁶⁻⁴⁸ Although NETs have only recently been linked to SLE, they present an intriguing and possibly significant mechanism that might account for observed alterations in immune function. They have the capacity to induce production of type I IFN by pDCs, serve as a source of relevant self-antigens for presentation to T lymphocytes, and mediate vascular damage and thrombosis.⁴⁹

As described earlier, the elucidation of a significant role for the nucleic acid-sensing TLRs in recent years has drawn attention to the important role of autoantigen in driving disease in lupus. The contribution of apoptotic debris, either through increased apoptosis and/or impaired clearance of apoptotic cells, has been assumed for a number of years to be at least one likely mechanism that drives immune system activation and focuses its specificity on nucleic acids and their associated proteins. Apoptotic blebs are enriched in the typical targets of autoantibodies such as Ro and Sm. Recent attention on so-called *microparticles*, small membrane-enclosed particles released by activated and dying cells, has generated data demonstrating binding of those particles by some autoantibodies in lupus plasma.⁵⁰ A combination of increased generation of nuclear material, perhaps modified, and impaired clearance may be important mechanisms of lupus immunopathogenesis. The role of C1q and complement components in the clearance of apoptotic debris has been suggested as an explanation for the strong association of C1q, C2, and C4 deficiencies with SLE.⁵¹ A second role for complement components that likely reduces the pathogenicity of immune complexes is the capacity of complement to solubilize immune complexes, reducing the likelihood that those complexes would deposit in tissue and cause damage.⁵²

ADAPTIVE IMMUNE SYSTEM ALTERATIONS IN SYSTEMIC LUPUS ERYTHEMATOSUS

T cell function has been carefully studied in SLE patients for several decades, and deficiencies or alterations in signaling pathways, production of cytokines, cell proliferation, and regulatory functions have been documented.⁵³ CD4⁺ T cells are viewed as a requirement for development of lupus on the basis of their essential role in providing helper signals that

drive differentiation of B cells to autoantibody-producing cells. Although some in vitro experiments have supported the capacity of cytokines such as IL-21 and B cell activating factor (BAFF)/B lymphocyte stimulator (BLyS) and TLR ligands to mediate antibody production by B cells, T cells are recognized as the most efficient drivers of B cell differentiation.⁵⁴

The activation status and signaling mechanisms of lupus T cells are distinct from those of T cells from healthy individuals. Among the alterations in function is decreased proliferation in response to self-non-T cells or allogeneic-non-T cells or in response to presentation of soluble antigens. In contrast, T cell proliferation induced by direct activation of the T cell antigen receptor is at least as strong as observed in control cells. Lupus T cells readily express CD40 ligand (CD154) after activation and maintain expression of that important co-stimulatory molecule longer than control T cells, leading to augmented help for activation and differentiation of B cells exposed to those T cells. Another long-standing observation is that lupus T cells produce less IL-2 than control T cells, perhaps one factor that contributes to impaired generation of IL-2-dependent T regulatory cells. The molecular basis of the altered T cell activation in lupus patients is complex, but at least one factor might be the observed substitution of the T cell receptor zeta chain with the common gamma chain that is a component of the Fc receptor signaling machinery. Correction of this defect can normalize T cell signaling and IL-2 production.⁵⁵ Augmented calcium responses following T cell receptor ligation have been observed, and hyperpolarization of mitochondria in T cells has been associated with altered T cell activation and function.⁵⁶

An interesting observation from studies of lupus T cells might reflect more global epigenetic alterations to the lupus genome that impact autoimmunity. Treatment of mouse and human T cells with 5-azacytidine resulted in increased expression of the lymphocyte function antigen-1 (LFA1; CD11a) adhesion molecule and increased proliferative responses to self-non-T cells.⁵⁷ Lupus T cells studied ex vivo show hypomethylation of CG-rich areas of the genome, and a recent report of genome methylation in identical twins discordant for lupus demonstrated relatively less methylation of the twin with active lupus.²⁴ Multiple mechanisms have been postulated to contribute to DNA demethylation in lupus lymphocytes including increased expression of growth arrest and DNA damage-induced 45alpha (GADD45alpha), a protein that removes methyl groups from DNA, decreased expression of DNMT1, and ERK pathway signaling.³⁴

Generalized lymphopenia is typical of SLE, but expansions of specific T cell populations have been described. The recently documented T follicular helper population, characterized by expression of ICOS, CXCR5, and Bcl6 and by production of IL-21, mediates important signals that promote differentiation of autoantigen-specific B cells.^{58,59} A population of CD8⁺ cells with a memory phenotype is associated with poor prognosis, possibly based on tissue damage mediated by those cells.⁶⁰

The regulation and function of T regulatory cells (Tregs), with capacity to suppress immune responses, and Th17 cells, which promote inflammation by production of IL-17, have been intensively studied in recent years. Some studies of

lupus patients do show a relative depletion of Tregs and increased Th17 cells and IL-17.⁶¹ The functional impact of those alterations in human lupus is still not clear.

Cytokine production is altered in SLE, with decreased production of IL-2 a characteristic feature of patient T cells, as it is of individuals carrying the HLA 8.1 haplotype.⁴ Although this deficiency in IL-2 was initially linked to the often poor proliferative responses of lupus T cells stimulated with autologous or allogeneic T cells or soluble antigen, the recognition that IL-2 is important for maintenance of T regulatory cells suggests another mechanism through which impaired production of IL-2 might contribute to immune system activation and autoimmunity.⁶²

B cell regulation is also impaired in SLE, contributing to differentiation to production of autoantibodies and cytokines. The activated phenotype of SLE B cells has the potential to promote efficient presentation of specific self-antigens to T cells. It has not been entirely clear whether altered B cell function is strictly secondary to increased availability of T cell help, B cell survival, proliferation and differentiation factors, and signaling through TLRs or whether primary B cell dysfunction also contributes to autoimmunity. Recent studies characterizing the B cell repertoire using single-cell polymerase chain reaction and cloning of individual immunoglobulin transcripts will permit improved understanding of the role of altered B cell tolerance mechanisms in the bone marrow versus secondary effects of T cell and cytokine help in generating self-reactive antibody specificities. BAFF/BLyS, IL-10, and IL-21 are among the candidate therapeutic targets that could modify the B cell differentiation program, a suggestion supported by clinical studies of BAFF/BLyS blockade. An additional approach toward improved regulation of B cell function is suggested by recent data demonstrating an association between vitamin D deficiency and presence of antinuclear antibodies in healthy individuals and increased B cell activation and serum type I IFN activity in vitamin D–deficient SLE patients.⁶³

The baseline activation status of lupus B cells, as well as their response to antigen stimulation, is altered when compared with B cells from healthy individuals, and current studies are exploring the functional implications of lupus-associated genetic variants in several kinases, phosphatases, and adaptor molecules such as BLK, BANK, and PTPN22 for B cell function. Studies of the risk variant of PTPN22 in B cells from healthy subjects point to the influence of that lupus-associated variant on impaired counterselection of self-reactive B cells.⁶⁴ LYN deficiency in mice is associated with a lupus-like phenotype, and similar deficiencies in the LYN kinase have been described in lupus B cells.⁶⁵ Polymorphisms in the gene encoding Lyn studied in European-descent individuals could potentially impact B cell signaling and autoimmunity.⁶⁶ The gene encoding the inhibitory Fc receptor, FCGR2B, is polymorphic, and several variants have been associated with SLE.^{67,68} SLE B cells show decreased expression of this FcR and altered cytokine production when engaged by immune complexes. Interestingly, the inhibitory capacity of FcγRIIb can be exploited using an engineered bifunctional antibody that coligates CD19 and FcγRIIb.⁶⁹ This antibody suppressed B cell functions in a mouse grafted with human B cells.

Current investigations of antibody-producing cells are defining several categories of B lineage cells that contribute to autoimmunity and disease. Long-lived plasma cells that are maintained by chemokines and stromal cell products in protective niches in the bone marrow are proposed as sources of those lupus autoantibodies such as anti-Sm and anti-Ro that are chronically maintained at fairly constant levels. Those antibodies have been refractory to modulation by immunosuppressive or B cell depletion therapy.⁷⁰ In contrast, circulating preplasma cells or plasmablasts are sources of anti-dsDNA antibodies that fluctuate in some patients in association with variations in disease activity and might be more amenable to anti-B cell therapy.⁷¹

The T and B cell alterations that have been described in studies of lupus immune function are undoubtedly a reflection of multiple genetic variations that play out in altering threshold for cell activation and efficiency of cell signaling. They are also the result of interactions among those lymphocytes, along with antigen-presenting cells and their products, that over time amplify the overall level of immune activation. Increased production of type I IFN and presence of antinuclear antibodies in healthy family members of lupus patients likely reflect the consequences of genetic variations that are among the factors that predispose to SLE. When the circuits of immune activation are amplified by environmental triggers, conditions are in place to generate the characteristic T and B cell autoimmunity that is required for tissue damage and disease.

AUTOIMMUNITY IN SYSTEMIC LUPUS ERYTHEMATOSUS

Autoantibodies are traditionally viewed as essential mediators of pathology in SLE, particularly when they are in the form of immune complexes. Virtually all lupus patients demonstrate a positive antinuclear antibody test, and the majority of patients have one or more of the characteristic autoantibody specificities that have been associated with lupus (see also Chapter 55). Among those, anti-dsDNA and anti-Smith (Sm) are most specific for SLE. Interestingly, those specificities have been linked functionally in murine studies that demonstrate that dsDNA can bind to a peptide comprising amino acids 83-119 of the SmD1 protein, and T cells specific for that peptide provide help for production of anti-dsDNA antibody.^{72,73} Anti-Ro, anti-La, and anti-RNP antibodies are characteristic of SLE but are also seen in other systemic autoimmune diseases. These characteristic autoantibodies in SLE can be categorized in relation to their targets including DNA and DNA-binding proteins, typically aggregated in nucleosomes that contain histones; RNA and RNA-associated proteins, typically aggregated in cytoplasmic or nuclear ribonucleoprotein particles; phospholipids exposed in plasma membranes and associated proteins such as β₂-glycoprotein I; and cell membrane proteins, typically those expressed on blood cells. Some of these self-antigens typically targeted by lupus autoantibodies are most likely accessed by antigen-presenting cells in the form of cell membrane–enclosed blebs derived from apoptotic cells or microparticles, small aggregates of cellular material derived from cells and generated after

flipping of phosphatidylserine to the outer aspect of the cell membrane in the setting of cell activation or apoptosis. Although some patients who present with a clinical picture characteristic of SLE do not have significant titers of those autoantibodies, it is likely that those patients have undefined autoimmunity targeted at unspecified antigens.

The pathogenic antibodies in SLE tend to be those produced by cells that are far along in the B cell differentiation process, either preplasma cells or plasma cells, and have undergone immunoglobulin class switching, a process that is driven by CD4⁺ T helper cells and in some cases by TLR ligands together with B cell differentiation factors such as IL-21 and BLyS/BAFF.⁵⁴ It is not possible to define the earliest step in the generation of pathogenic autoantibodies, and in fact it is probable that the generation of autoimmunity can begin in any number of ways. Presentation of self-antigen by an excessively activated antigen-presenting cell, stochastic activation of low-avidity self-reactive T cells that are present in healthy individuals but have the potential to expand and drive differentiation of B cells with broad specificity for self-antigens, or direct activation of self-reactive B cells in the presence of activating TLR ligands such as those provided by demethylated CpG-rich DNA from bacteria or viruses or self-derived nuclear debris might all be starting points for development of pathogenic autoimmunity. The process might begin with production of type I IFN by a virus-infected cell or a cell with impaired degradation of intracellular nucleic acids, altering the threshold for activation of the immune system by subsequent exposures to self-antigens. Less important than the precise starting point is the observation that autoimmunity develops and builds over time, with presence of autoantibodies observed more than 5 years before clinical manifestations of disease appear and the range of specificities of antigens targeted expanding over time.⁷⁴ The data from analysis of prevalence of several lupus autoantibodies among sera collected from members of the military who later developed SLE demonstrate an intriguing sequence, with anti-Ro antibodies typically presenting earliest, anti-dsDNA antibodies appearing several years later, and anti-Sm, the antibody specificity most specific for a diagnosis of SLE, appearing approximately at the time of clinical diagnosis. This pattern, along with studies from murine models demonstrating determinant spreading of autoantibody specificities not only to distinct proteins within a nucleic acid–protein particle but also to other self-antigen targets, provides clues to lupus pathogenesis that are not yet understood but hold promise for future breakthroughs in elucidating important pathogenic mechanisms.⁷⁵ Additional autoantibody specificities that are associated with lupus activity and with proliferative lupus nephritis and are thought to be pathogenic include those reactive with C1q. Anti-C1q antibodies appear to recognize neopeptides of C1q when it is bound to early apoptotic cells.⁷⁶

A shift from a predominant polyclonal IgM picture toward polyclonal IgG, driven by T cell help and cytokines, occurs over time in most patients with lupus and with development of tissue pathology and damage. In fact, some IgM antibodies that have self-reactivity are viewed as protective, with the switch from IgM to IgG or IgA representing an important point of altered immune regulation that

contributes to the immunopathogenesis of SLE. Some of these IgM natural antibodies react with apoptotic cells and actually inhibit their activation through TLRs.⁷⁷

In addition to immunoglobulin class, with class-switched antibodies better able to access extravascular spaces compared with IgM antibodies, amino acid sequence and charge of the antigen-binding site can influence pathogenicity. Arginines in the CDR3 region of anti-dsDNA antibodies are characteristic and influence binding to their DNA target. Molecular mimicry is a concept that has been applied to reactivity of antibodies specific for a microbial protein that also react with self-antigens, but the concept can also be applied to those antibodies that unexpectedly bind to two distinct self-antigens. For example, some anti-dsDNA antibodies were found to bind to a peptide that is a feature of glutamate receptors on central nervous system neurons.⁷⁸ Beyond features of Ig class and antigen-binding site that influence access to tissue and affinity of binding, glycosylation and complement-fixing capacity are important determinants of the antibody's capacity to bind to Fc receptors and promote complement activation, resulting in target cell death or inflammation.

The role of SLE autoantibodies in the pathogenesis of the disease has traditionally focused on the deposition of immune complexes in skin, renal glomerulus, and other sites of tissue injury, along with a potential contribution of direct targeting of antibodies to local or “planted” antigens. But in recent years, with the recognition that nucleic acid-containing immune complexes can directly induce cell signaling and new gene transcription after accessing endosomal TLRs, an additional important pathogenic role for autoantibodies as immune modulators has been defined.

Particular lupus autoantibody specificities have been associated with specific clinical manifestations of disease (Table 79-4). Perhaps the best developed characterization of the mechanisms by which an autoantibody mediates disease is the role of maternal-derived anti-Ro antibody in the neonatal lupus syndrome. After transplacental transfer of anti-Ro antibody, RNA-containing immune complexes are proposed to form, activating the production of cytokines that contribute to fibrosis of the cardiac conduction system.⁷⁹ This scenario, similar to that which mediates production of type I IFN by pDCs, identifies nucleic acid–autoantibody immune complexes as regulators of cytokine production that results in tissue damage. Anti-Ro and anti-La antibodies, although common to several autoimmune diseases, are also characteristic in association with sicca symptoms, subacute cutaneous lupus, and, as noted, in neonatal lupus. Anti-RNP antibodies are seen in both SLE and mixed connective tissue disease.

Antiphospholipid antibodies, with lupus anticoagulant the most informative antibody profile, contribute to placental damage and vascular thrombosis, as well as thrombocytopenia in the antiphospholipid syndrome and in some patients with lupus. Recent studies in a murine model indicate that tissue damage and thrombosis depend on activation of the complement system by the antiphospholipid antibodies.⁸⁰ Similar mechanisms might be relevant in forms of lupus renal disease characterized by microangiopathy.

Table 79-4 Correlation among Clinical Manifestations of Systemic Lupus Erythematosus and Autoantibodies, Immune Complexes, and T Cells

Manifestation	Autoantibodies	Immune Complexes	T Cells
Nephritis	Anti-dsDNA Anti-Ro Anti-C1q Ids 16/6, 3I and GN2 ?	+	+
Arthritis		+	+
Dermatitis	Anti-Ro Anti-dsDNA Id 16/6		+
Vasculitis	Anti-Ro	+	+
Central nervous system	Antiribosomal P Antineuronal Anti-NR2	+	
Hematologic: Lymphopenia Hemolysis Thrombocytopenia	Antilymphocyte Antierthrocyte Antiplatelet	+	
Clotting	Antiphospholipid		
Fetal loss	Antiphospholipid		
Neonatal lupus	Anti-Ro		
Sicca syndrome	Anti-Ro		+
Mild disease	Anti-RNP without other autoantibody except antinuclear antibody		

MECHANISMS OF TARGET ORGAN DAMAGE

Clinical disease is ultimately a reflection of tissue damage mediated by the inflammatory sequelae of the described autoimmunity and immune system activation, along with an exaggerated or aberrant repair response. The classic view of the mechanisms that result in tissue damage involves activation of the complement system by immune complexes deposited in tissue, as well as release of products of phagocytes including enzymes released from neutrophil granules and reactive oxygen intermediates from macrophages. Recent studies in mouse and human systems involving extensive analysis of renal infiltrating cells at various points in the disease process have identified a monocyte population that has undergone differentiation to generate a functional phenotype that mediates what is apparently uncontrolled tissue repair, contributing to sclerosis and organ dysfunction.⁸¹ Studies in a murine model have shown that IFN- α can also contribute to development of crescents in lupus kidneys.⁸²

The role of the vasculature as a significant target organ contributing to disease in lupus has once again come to the fore, after several decades that have focused predominantly on the immune system and the contributions of autoantibodies to pathology.⁸³ Altered structure and function of both venous and arterial vessels have been noted for many years including the periarteriolar concentric onion skinning seen in spleen, microangiopathy and associated microthrombi seen in some organs, and the endothelial dysfunction that has been associated with premature atherosclerosis in lupus patients. Recent studies have focused on the potential role of type I IFN on endothelial cells and endothelial cell progenitor cells and have postulated that increased production of IFN is at least one contributor to impaired vascular repair.⁸⁴ A role for granulocytes and proinflammatory

lipids has also been proposed.^{49,85} Characterization of the micropathology of the vasculature in Degos disease, a syndrome with some common pathologic features with SLE, has drawn attention to the association of activation of the IFN pathway with vascular sclerosis and endothelial damage.⁸⁶ A possible direct contribution of type I IFN to vascular injury supplements the previously described role of complement activation products C3a and C5a and expression of endothelial cell surface adhesion molecules E-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1) in lupus flares.

SUMMARY

Considerable gains in understanding mechanisms of lupus pathogenesis have established the knowledge base that will underlie future advances in development of targeted therapies that will improve patient outcomes. The recognition of a central role for innate immune system activation including the role of type I IFN in lupus pathogenesis has been a major advance in recent years. Rapid progress in characterizing the genetic variants that are associated with a diagnosis of lupus has provided strong support for alterations in molecular pathways that regulate nucleic acid degradation, TLR signaling and lymphocyte activation thresholds, and signaling efficiency as important mechanisms that determine disease susceptibility. The products of the immune system including autoantibodies and their immune complexes, cytokines, and complement components, along with proinflammatory mediators and reactive oxygen products released from neutrophils and macrophages, remain key mediators of tissue damage. But an additional pathogenic role for nucleic acid-containing immune complexes as immune modulators through their important capacity to access and activate endosomal TLRs is an important new

concept that can guide future therapeutic approaches. Targeting the components of innate immune system activation that affect the TLR pathway along with modulation of T cell help for B cell differentiation to autoantibody-producing cells would appear to be a rational therapeutic strategy in light of our current understanding of pathogenic mechanisms.

Clinical Features of Systemic Lupus Erythematosus

MARIA DALL'ERA • DAVID WOFSY

KEY POINTS

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized by a relapsing-remitting course and a highly variable prognosis.

It is characterized by the production of a broad array of autoantibodies, with antinuclear antibodies having the greatest sensitivity for the diagnosis and anti-double-stranded DNA and anti-Smith antibodies having the greatest specificity.

Women of childbearing age and African-American, Asian, and Hispanic populations have the highest prevalence of disease.

Constitutional symptoms, rash, mucosal ulcers, inflammatory polyarthritis, photosensitivity, and serositis are the most common clinical features of the disease.

Lupus nephritis is the most common of the potentially life-threatening manifestations.

Atherosclerosis, a complication of long-standing SLE, requires aggressive risk factor modification.

CLASSIFICATION CRITERIA

Systemic lupus erythematosus (SLE) is the prototypic systemic autoimmune disease characterized by diverse multisystem involvement and the production of an array of autoantibodies. Clinical features in individual patients can be quite variable, ranging from mild joint and skin involvement to severe life-threatening internal organ disease. Criteria for the classification of SLE were initially developed by the American College of Rheumatology (ACR) in 1971, revised in 1982, and revised for a second time in 1997^{1,2} (Table 80-1). A person must fulfill 4 of 11 criteria to be classified as SLE, all other reasonable diagnoses having been excluded. A patient does not have to manifest all 4 criteria simultaneously; the required 4 of 11 criteria can be fulfilled over a period of weeks or years. The ACR criteria were developed as a means of classifying patients with SLE for the purpose of inclusion in clinical and epidemiologic studies. In clinical practice, these criteria are often cited to support a diagnosis of SLE. However, it should be emphasized that fulfillment of these classification criteria is not an absolute requirement for diagnosis. Rather, diagnosis typically rests on the judgment of an experienced clinician who recognizes a characteristic constellation of symptoms and signs in the setting of supportive serologic studies, after exclusion of alternative differential diagnostic possibilities. Recently, a concerted effort has been made to further revise the classification criteria, for example, to make lupus nephritis a “stand-alone” criterion, to increase the weight of

neurologic manifestations, and/or to add a low-complement criterion. These proposed changes to the classification criteria are currently in development.

EPIDEMIOLOGY

Prevalence and incidence rates of SLE vary widely in the literature. Reported prevalence frequencies range from 20 to 240 per 100,000 persons, and reported incidence rates range from 1 to 10 per 100,000 person-years.³ This variation is partly due to methodological differences between studies (e.g., different case definitions of SLE and methods of case ascertainment). One study from Rochester, Minnesota, determined that the incidence of SLE increased almost fourfold between the time periods of 1950 to 1979 and 1980 to 1992.⁴ This increase in reported incidence may reflect a combination of factors, including an actual increase in disease, changes in population demographics, more widespread case-finding efforts, and detection of milder cases.

Prevalence and incidence of SLE vary across gender, geographic regions, and racial/ethnic groups. SLE demonstrates a striking female predominance with a peak incidence during reproductive years. The degree of female predominance varies with age. The female-to-male ratio is 10 to 15:1 in adults, 3:1 in older-onset SLE, and 8:1 in children.⁵ The prevalence of SLE is believed to be approximately three- to fourfold higher in African-American, Asian, and Hispanic populations compared with white populations.⁶ SLE is rare among blacks in Africa.

Most SLE patients present with their disease between 15 and 64 years of age.⁷ Patients with pediatric-onset SLE (<16 years old) are more likely to be African-American than those with later-onset SLE.⁷ SLE tends to be more severe in men and in pediatric patients. Late-onset SLE (>50 years old) is characterized by a more insidious onset with a higher occurrence of serositis and pulmonary involvement and a lower incidence of malar rash, photosensitivity, alopecia, Raynaud's phenomenon, neuropsychiatric disease, and nephritis.⁷

CLINICAL FEATURES

Systemic lupus erythematosus has protean clinical manifestations that may differ dramatically from patient to patient. Just as the signs and symptoms of SLE vary widely among patients, so too does the severity of disease. Some patients with lupus will have relatively mild disease that never threatens a life-sustaining organ; other patients will progress rapidly to life-threatening disease.

The great variability in the expression and severity of SLE constitutes a major challenge to accurate diagnosis.

Table 80-1 1997 Update of the 1982 Revised American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus*

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scale and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	a. Pleuritis-convincing history of pleuritic chest pain or rub heard by a physician or evidence of pleural effusions <i>or</i> b. Pericarditis-documented by electrocardiogram or rub or evidence of pericardial effusion
Renal disorder	a. Persistent proteinuria >0.5 g/day, >3+ if quantification not performed <i>or</i> b. Cellular casts: may be red blood cell, hemoglobin, granular tubular, or mixed
Neurologic disorder	a. Seizures: in the absence of offending drugs or known metabolic derangements (e.g., uremia, acidosis, electrolyte imbalance) <i>or</i> b. Psychosis: in the absence of offending drugs or known metabolic derangements (e.g., uremia, acidosis, electrolyte imbalance)
Hematologic disorder	a. Hemolytic anemia with reticulocytosis <i>or</i> b. Leukopenia <4000/mm ³ <i>or</i> c. Lymphopenia <1500/mm ³ <i>or</i> d. Thrombocytopenia <100,000/mm ³ in the absence of offending drugs
Immunologic disorder	a. Anti-DNA: antibody to native DNA in abnormal titer <i>or</i> b. Anti-Smith: presence of antibody to Sm nuclear antigen <i>or</i> c. Positive finding of antiphospholipid antibodies based on (1) abnormal serum concentration of IgG or IgM anticardiolipin antibodies, (2) positive test result for lupus anticoagulant using a standard method, or (3) false-positive serologic test for syphilis known to be positive for at least 6 mo and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
Positive antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndromes

*The presence of four or more criteria is required for systemic lupus erythematosus classification. Exclude all other reasonable diagnoses.

Although it is difficult to pinpoint their precise frequencies, it is clear that the most common presenting manifestations are constitutional symptoms (fever, fatigue, and/or weight loss), cutaneous manifestations (e.g., malar rash), and articular manifestations (arthritis and/or arthralgia). Each of these manifestations appears to be present in at least 50% of lupus patients at the time of diagnosis. The other clinical features of SLE are much less likely to be presenting manifestations, although virtually any of them might be the first clue to the correct diagnosis. More commonly, these manifestations appear over time as the disease evolves. Taken together, various descriptive studies in the literature^{1,8-12} support a cumulative frequency of symptoms and signs that is summarized in Table 80-2.

Table 80-2 Frequencies of Various Manifestations of Systemic Lupus Erythematosus*

Manifestation	Frequency
Constitutional symptoms (fatigue, fever, weight loss)	90%-95%
Mucocutaneous involvement (malar rash, alopecia, mucosal ulcers, discoid lesions, etc.)	80%-90%
Musculoskeletal involvement (arthritis/arthralgia, avascular necrosis, myositis, etc.)	80%-90%
Serositis (pleuritis, pericarditis, peritonitis)	50%-70%
Glomerulonephritis	40%-60%
Neuropsychiatric involvement (cognitive impairment, depression, psychosis, seizures, stroke, demyelinating syndromes, peripheral neuropathy, etc.)	40%-60%
Autoimmune cytopenia (anemia, thrombocytopenia)	20%-30%

*Systemic lupus erythematosus is a heterogeneous disease that can affect virtually any organ system in variable ways.

Mucocutaneous Involvement

Mucocutaneous involvement is very common in SLE. Gilliam and colleagues have categorized cutaneous lupus erythematosus (LE) lesions as “lupus specific” or “lupus non-specific” based on the histopathologic finding of interface dermatitis^{13,14} (Table 80-3). The presence of lupus-specific lesions confirms the diagnosis of cutaneous LE; lupus non-specific lesions can occur in diseases other than lupus. Lupus-specific lesions are further subdivided into acute lupus erythematosus (ACLE), subacute lupus erythematosus (SCLE), and chronic cutaneous lupus erythematosus (CCLE) lesions, based on additional clinical and histopathologic information. Discoid lupus is the most common subtype of CCLE. SCLE and CCLE can occur as distinct isolated entities or as one of several manifestations of SLE. The risk of SLE varies with each cutaneous subset. One study of 161 patients with lupus-specific lesions showed that the classification criteria for SLE were present in 72% of patients with ACLE, 58% with SCLE, 28% with any form of discoid lupus, and 6% with localized discoid lupus confined to head and neck. Patients commonly displayed more than one type of cutaneous lesion.¹⁵

Acute Cutaneous Lupus Erythematosus

Acute cutaneous lupus erythematosus (ACLE) lesions can be localized or generalized. The hallmark feature of ACLE is localized to the malar region (“butterfly rash”) and is characterized by confluent, macular or papular erythema lasting days to weeks that occurs symmetrically on the cheeks and bridge of the nose, sparing the nasolabial folds (Figure 80-1). Induration and scaling may occur. The malar rash of SLE can be mimicked by a variety of other facial

Table 80-3 Gilliam Classification of Skin Lesions Associated with Lupus

A. Lupus erythematosus (LE)-specific skin lesions	
1.	Acute cutaneous LE (ACLE)
	Localized ACLE
	Generalized ACLE
2.	Subacute cutaneous LE (SCLE)
	Annular SCLE
	Papulosquamous SCLE
3.	Chronic cutaneous LE (CCLE)
	Classical discoid LE (DLE): (a) localized; (b) generalized
	Hypertrophic DLE/verruccous DLE
	Lupus panniculitis/profundus
	Mucosal DLE
	LE tumidus
	Chilblain LE
	Lichenoid DLE (DLE-lichen planus overlap)
B. LE-nonspecific skin lesions	
1.	Cutaneous vascular disease
	Vasculitis
	Leukocytoclastic vasculitis
	Polyarteritis nodosa–like
	Vasculopathy
	Degos disease–like
	Atrophe blanche–like
	Periungal telangiectasia
	Livedo reticularis
	Thrombophlebitis
	Raynaud’s phenomenon
	Erythromelalgia
2.	Nonscarring alopecia
	“Lupus hair”
	Telogen effluvium
	Alopecia areata
3.	Sclerodactyly
4.	Rheumatoid nodules
5.	Calcinosis cutis
6.	LE-nonspecific bullous lesions
7.	Urticaria
8.	Papulonodular mucinosis
9.	Cutis laxa/anetoderma
10.	Acanthosis nigricans (type B insulin resistance)
11.	Erythema multiforme (Rowell’s syndrome)
12.	Leg ulcers
13.	Lichen planus

rashes, including acne, rosacea, seborrheic dermatitis, perioral dermatitis, atopic dermatitis, and erysipelas. If the diagnosis remains uncertain after an extensive clinical and serologic evaluation, biopsy of the rash can aid in distinguishing cutaneous lupus from other dermatologic conditions. It is important to remember that other forms of lupus-specific skin lesions such as discoid lupus can also occur in the malar distribution.

The generalized form of ACLE refers to widespread macular or maculopapular erythema occurring in a photosensitive distribution on any area of the body. The palmar surfaces, dorsa of the hands, and extensor surfaces of the fingers are commonly involved. In contrast to Gottron’s papules of dermatomyositis, the erythema of ACLE spares the metacarpalphalangeal joints and typically is located between the interphalangeal joints. In severe forms of ACLE, a widespread bullous eruption similar to toxic epidermal necrolysis (TEN) can occur. ACLE lesions heal without scarring, although temporary postinflammatory hyperpigmentation may be observed.

Subacute Cutaneous Lupus Erythematosus

Subacute cutaneous lupus erythematosus (SCLE) is characterized by the presence of nonscarring, photosensitive lesions that can take one of two distinct forms: (1) papulosquamous lesions that resemble psoriasis, or (2) annular-polycyclic lesions with peripheral scale and central clearing (Figure 80-2). These two forms can occur concurrently in the same patient. SCLE has a predilection for the back, neck, shoulders, and extensor surfaces of the arms and usually spares the face. The lesions typically last for weeks to months and heal without scarring. Uncommonly, a severe TEN-like eruption can evolve from SCLE lesions after sun exposure.¹⁶ SCLE, particularly the annular subtype, is strongly associated with the presence of anti-SSA/Ro antibody.¹⁷ Several drugs are known to induce SCLE; angiotensin-converting enzyme inhibitors, terbinafine, hydrochlorothiazide, and calcium channel blockers are common culprits. Finally, SCLE has been implicated as a paraneoplastic syndrome.¹⁸

Figure 80-1 Localized acute cutaneous lupus erythematosus (malar rash, butterfly rash). This lesion is characterized by macular or papular erythema in a malar distribution, sparing the nasolabial folds.

Figure 80-2 Subacute cutaneous lupus (papulosquamous variant). Lesions typically involve the back, neck, shoulders, and extensor surfaces of the arms and usually spare the central area of the face. Lesions heal without scar.

Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous lupus erythematosus (CCLE) refers to a variety of subtypes of photosensitive lesions that can lead to skin atrophy and scar and that may persist for several months. Discoid lupus (DLE) is the most common subtype of CCLE and is subdivided into localized discoid lupus (limited to head and neck) and generalized discoid (occurring above and below the neck) (Figures 80-3 and 80-4). The term “discoid” refers to the sharply demarcated disk-shaped appearance of the lesions. The lesions are raised, erythematous plaques with adherent scale that commonly occur on the scalp, face, and neck. The cheeks, nose, ears, and upper lip are classic locations. Typically, a raised, erythematous border denotes the actively expanding component. Follicular plugging is a characteristic finding. Left untreated, DLE can result in permanent alopecia and disfigurement. Squamous cell carcinoma has been described as a sequela of long-standing DLE; thus, active surveillance of known lesions and evaluation of changing lesions are critical.¹⁹ Other subtypes of DLE include mucosal DLE (described later) and hypertrophic LE. Hypertrophic LE consists of chronic, indurated lesions that are covered by hyperkeratotic, multilayered scales. These lesions can be a source of diagnostic confusion because they may visually and histologically resemble squamous cell carcinoma.²⁰

Other forms of CCLE include lupus panniculitis/profundus and chilblain lupus. Lupus panniculitis is a lobular panniculitis that has a predilection for the scalp, face, arms, buttocks, and thighs. When a cutaneous discoid lesion

Figure 80-3 Discoid lupus erythematosus involving the face and scalp. Discoid lesions are a form of chronic cutaneous lupus and are commonly found on the scalp, face, and external ears. If untreated, these lesions can lead to permanent alopecia and disfigurement.

Figure 80-4 Discoid lupus erythematosus involving the dorsa of the hands. The lesions spare the proximal interphalangeal joints, a characteristic feature of lupus-specific rashes.

overlies the panniculitis, the entity is referred to as *lupus profundus*.²¹ Biopsy is often necessary to secure the diagnosis because reports have described T cell lymphoma mimicking panniculitis. However, biopsy should be performed carefully because the lesions have a tendency to break down. Lupus panniculitis is one of the few panniculitides that can occur above the waist. Lupus panniculitis is associated with low risk of concomitant SLE. Chilblain lupus manifests as tender, erythematous, or violaceous papules occurring on acral areas, especially fingers, toes, heels, nose, and ears. The lesions are brought on by cold, damp air.

Other Systemic Lupus Erythematosus Skin Lesions

SLE patients can develop lupus-nonspecific skin lesions such as cutaneous leukocytoclastic vasculitis, bullous lesions, periungal erythema, and livedo reticularis. Cutaneous leukocytoclastic vasculitis most commonly presents as palpable purpura on the lower extremities. Bullous lupus erythematosus is a rare cutaneous manifestation characterized by subepidermal vesiculobullous skin changes. It is manifested by a nonscarring bullous eruption²² (Figure 80-5). SLE may be associated with other bullous disorders such as bullous pemphigoid and dermatitis herpetiformis. The physical examination finding of periungal erythema represents dilation of the capillaries at the base of the nail. These capillaries can be visualized at the bedside with a dermatoscope or ophthalmoscope. Other disorders associated with periungal erythema include scleroderma and mixed connective tissue disease (MCTD). Unlike scleroderma and MCTD, SLE is not associated with capillary dropout. Livedo reticularis is characterized by an erythematous to violaceous reticular or net-like pattern of the skin. It is highly associated with the antiphospholipid antibody syndrome.

Photosensitivity

Photosensitivity occurs frequently in SLE. In one study, photoprovocation testing caused an abnormal skin reaction to ultraviolet A, ultraviolet B, or visible light in greater than 90% of lupus patients.²³ Most abnormal skin reactions

Figure 80-5 Bullous lupus erythematosus. These lesions are a rare manifestation of lupus and are characterized by nonscarring bullous lesions.

occurred 1 to 2 weeks after exposure to light and persisted for weeks to months. Photosensitive patients may report worsening of their systemic disease symptoms such as fatigue and joint pain following sun exposure. During evaluation of a photosensitive patient, polymorphous light eruption (PMLE) and phototoxic medications are important diagnostic considerations.²⁴ Accurate differentiation between PMLE and lupus is essential because PMLE is treated by ultraviolet radiation phototherapy, but lupus is worsened by it. PMLE can occur concomitantly in patients with known SLE.

Alopecia

Scarring alopecia is a common complication of discoid lupus. Scalp discoid lesions most frequently develop on the vertex and parietal areas.²⁵ Nonscarring alopecia in SLE patients can take several forms. “Lupus hair” is characterized by short, irregularly sized hair at the frontal hairline and is associated with active systemic disease.²⁶ Telogen effluvium manifests as diffuse hair thinning. Lastly, the incidence of alopecia areata (discrete areas of hair loss) is believed to be increased in SLE.²⁷

Mucosal Ulcers

SLE patients commonly develop nasal or oral lesions that represent the mucosal counterparts of cutaneous lupus.²⁸ Acute oral lupus lesions present as red macules, palatal erythema or petechiae, erosions, or ulcerations. These lesions are usually painless. Subacute oral lesions are rare, and are characterized by well-demarcated, round, red patches. Oral discoid lesions present as painful, well-demarcated, round, red lesions with white radiating hyperkeratotic striae. When the lesions evolve, they may take on a honeycomb appearance. Oral discoid lupus frequently involves the lip and spreads from the vermilion border to the skin of the lip. Lupus oral ulcers have a gradual onset and can occur anywhere on the oral mucosa, the most common locations being the hard palate, buccal mucosa, and vermilion border.²⁹ These lesions are most commonly unilateral or asymmetric. The relationship between the

presence of oral lesions and systemic disease activity remains unclear. Note that oral candidiasis and oral lichen planus can take on a similar appearance to SLE oral ulcers. The histopathology and immunopathology of mucosal lesions are similar to the alterations seen in the skin. Vasculitis is absent.

DERMATOPATHOLOGY AND IMMUNOPATHOLOGY

A skin biopsy is useful in the diagnosis of cutaneous lupus in the setting of an atypical clinical presentation. Immunofluorescence should always be performed along with conventional histology. “Lupus-specific” skin lesions are characterized by an interface dermatitis consisting of a mononuclear cell infiltrate at the dermal-epidermal junction. Other pathologic findings present in lupus skin lesions include basal layer vasculopathic degeneration of keratinocytes, perivascular and periadnexal inflammation, follicular plugging, mucin deposition, and hyperkeratosis. These findings occur to different degrees in various lupus-specific skin lesions, with discoid lesions showing the most profound changes.³⁰ In contrast, early ACLE lesions may have minimal histopathologic findings and only a sparse lymphocytic infiltrate.

Immunofluorescence demonstrates granular deposition of immunoglobulin and complement components along the dermal-epidermal junction. Immunoglobulin (Ig)G and IgM are the most common immunoglobulin subtypes deposited. Various complement components including C3, C1q, and the membrane attack complex have also been identified. Direct immunofluorescence (DIF) of nonlesional, sun-exposed skin is called the *lupus band test*. Although a positive lupus band test is often seen in patients with SLE, this may also be seen in patients with other rheumatic diseases, as well as in healthy people. In one study, 20% of healthy young adults had a positive DIF in sun-exposed skin.³¹ It is important to note that serologic testing with antinuclear antibody (ANA), anti-double-stranded DNA (anti-dsDNA), and anti-Smith (anti-SM) has largely supplanted use of the lupus band test in confirming the diagnosis of SLE. DIF of nonlesional, sun-protected skin is believed to be more specific for SLE.

MUSCULOSKELETAL

Arthritis

Arthritis and arthralgias are very common manifestations of SLE, present in up to 90% of patients at some point during the course of their disease.³² Severity of involvement can range from mild joint pain to deforming arthritis. Although any joint can be involved, lupus arthritis is characterized by a symmetric, inflammatory arthritis predominantly affecting the knees, wrists, and small joints of the hands.³³ Synovial effusions are typically small and not as inflammatory as those present in rheumatoid arthritis. Hand deformities can occur as a result of ligamentous and/or joint capsule laxity and joint subluxation. This manifestation is called “Jacoud’s-like arthropathy” because it resembles the arthropathy that develops in patients with a history of rheumatic fever (Figure 80-6). Lupus hand deformities are reducible.

Figure 80-6 Jaccoud's-like arthropathy. These hand deformities resemble those that develop in patients with a history of rheumatic fever and are caused by ligamentous and/or joint capsule laxity. Deformities in the hands, such as ulnar drift at the metacarpophalangeal joints, swan neck and boutonniere deformities, and hyperextension at the interphalangeal joint of the thumb, closely resemble the deformities seen in rheumatoid arthritis. Absence of erosions on radiographs and their reducibility distinguish this condition from the deforming arthritis of rheumatoid arthritis. (Courtesy Dr. D. Vassilopoulos.)

Jaccoud's-like arthropathy sometimes occurs in the foot as well.³⁴

Although lupus arthritis is not classically associated with erosions on plain radiography, erosive disease has been described in a small subset of patients.³⁵ In addition, MRI studies have shown occasional erosions in some patients with lupus arthritis.³⁶ Erosive arthritis is more commonly a feature of MCTD. Some studies have demonstrated an association between lupus erosive arthritis and the presence of anticyclic citrullinated protein (anti-CCP) antibodies.³⁵ In addition to arthritis, tendinitis or tenosynovitis is frequently observed in SLE patients.³⁷ Tendon rupture is a very uncommon occurrence.

Synovial biopsies from lupus arthritis patients have shown a variety of abnormalities, including deposition of fibrin-like material, focal or diffuse synovial lining cell proliferation, vascular congestion, perivascular mononuclear cell infiltration, vasculitis, and obliteration of vessel lumina.³⁸ Radiographic studies of patients with SLE have revealed changes such as cystic bone lesions, periarticular soft tissue swelling, demineralization, acral sclerosis, joint subluxations, and erosions.^{39,40}

Avascular Necrosis

Avascular necrosis (AVN), also referred to as aseptic necrosis and ischemic necrosis, is a painful and disabling condition that occurs in some SLE patients.⁴¹ AVN is the end result of interruption of the blood supply to bone, leading to reactive hyperemia of adjacent bone, demineralization, and then collapse. The most commonly affected sites include the femoral heads, tibial plateaus, and femoral condyles, but smaller joints can be involved as well. AVN is often bilateral, and joint effusions may occur. AVN of the femoral head should be suspected in an SLE patient with groin pain that is worsened with weight bearing and movement of the hip. The pain may radiate down the side of the thigh, and a limp might be evident. Although both plain radiographs and magnetic resonance imaging (MRI) can be helpful in

the diagnosis of AVN, MRI is the more sensitive test. One prospective MRI study of 45 SLE patients on glucocorticoid therapy demonstrated that 34% of patients developed silent osteonecrosis of the femoral head.⁴² However, MRI studies may be too sensitive an indicator, in that some lupus patients with suggestive MRI findings never progress to clinical symptoms of AVN. Therefore, MRI findings should always be interpreted in the context of the clinical setting. The use of high doses of glucocorticoids is a well-known risk factor for the development of AVN, but AVN has also been described in SLE patients who have never used glucocorticoids. An MRI study of 72 newly diagnosed SLE patients demonstrated that AVN typically developed within the first 3 months of initiation of high-dose glucocorticoids.⁴³ Epidemiologic studies have shown that high disease activity as measured by the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and the use of cytotoxic medications are also associated with AVN.^{44,45}

Myositis

Although myalgias occur commonly in SLE, true myositis is relatively rare. One study of SLE patients at the National Institutes of Health (NIH) found a prevalence of myositis of 8%.⁴⁶ In most of those patients, myositis was one of the presenting features of SLE. Myositis usually involves the proximal upper and lower extremities. Histologic findings in SLE myositis are often less pronounced than those observed in polymyositis.

A biopsy study of 55 unselected SLE patients demonstrated that several pathologic changes, including type II fiber atrophy, lymphocytic vasculitis, and myositis, were increased in SLE patients compared with control patients.⁴⁷

It is important to distinguish myositis secondary to SLE from myopathy caused by glucocorticoids, antimalarial agents, or statins because the treatment is very different. Muscle enzymes such as creatine phosphokinase (CPK) and aldolase are typically normal in patients with both glucocorticoid- and hydroxychloroquine-induced myopathy. Biopsy specimens usually reveal characteristic findings, including vacuolar changes in hydroxychloroquine myopathy and type II fiber atrophy in glucocorticoid myopathy in the absence of inflammation. Finally, it is important to think broadly about other potential causes of myopathy and myositis in SLE patients, including thyroid disease, electrolyte abnormalities, and infectious myositis. One must also consider the possibility of MCTD because myositis can be a prominent feature of that disorder.

RENAL INVOLVEMENT

General Considerations

Renal involvement is common in SLE and is a significant cause of morbidity and mortality.⁴⁸ It is estimated that up to 90% of SLE patients will have pathologic evidence of renal involvement on biopsy, but only 50% will develop clinically significant nephritis. The clinical presentation of lupus nephritis is highly variable, ranging from asymptomatic hematuria and/or proteinuria to frank nephrotic syndrome to rapidly progressive glomerulonephritis with loss of renal function. Lupus nephritis typically develops within the first

36 months of the disease, although there are exceptions. Thus, periodic screening for the presence of nephritis is a critical component of the ongoing evaluation and management of SLE patients. Routine screening procedures include inquiring about new-onset polyuria, nocturia, or foamy urine and looking for the presence of hypertension or lower extremity edema. It is important to screen at regular intervals for the presence of proteinuria and/or hematuria and a change in serum creatinine; in active SLE patients, screening at 3-month intervals is prudent.

Types of Renal Involvement in Systemic Lupus Erythematosus

Several forms of renal involvement have been noted in SLE, including immune complex-mediated glomerulonephritis (most common form), tubulointerstitial disease, and vascular disease. Glomerulonephritis is characterized by immune complex deposition and inflammatory cell infiltration into the glomerulus. The pattern of glomerular injury is primarily related to the site of immune complex deposition. Tubulointerstitial and vascular disease can occur with or without immune complex-mediated glomerulonephritis. Tubulointerstitial disease has been observed in up to 66% of SLE renal biopsy specimens⁴⁹ and is characterized by inflammatory cell infiltrates, tubular damage, and interstitial fibrosis. The presence of tubulointerstitial disease is a strong predictor of poor long-term renal outcome.⁵⁰

Renal vascular lesions in SLE include “lupus vasculopathy,” thrombotic microangiopathy (TMA), vasculitis, and nonspecific vascular sclerosis.^{51,52} Lupus vasculopathy is defined as the presence of immunoglobulin and complement-containing hyaline thrombi within the glomerular capillary or arteriolar lumina. Inflammatory changes to the vascular wall are absent. TMA is characterized by the presence of fibrin thrombi within the glomerular capillary or arteriolar lumina and may be associated with the presence of antiphospholipid antibodies. The finding of TMA should prompt consideration of antiphospholipid antibody syndrome nephropathy (APSN). Although exceedingly rare, true vasculitis characterized by leukocyte infiltration and fibrinoid necrosis of arterial walls can occur. Nonspecific sclerotic vascular lesions characterized by fibrous intimal thickening are commonly observed. The presence of such vascular lesions is associated with decreased renal survival.⁵³ In addition to the lupus-related renal lesions described previously, SLE patients may develop renal abnormalities that are unrelated to their underlying SLE. Such pathologic lesions include focal segmental glomerulosclerosis (FSGS), hypertensive nephrosclerosis, and thin basement membrane disease.⁵⁴ In an SLE patient in whom renal disease is suspected, renal biopsy is critical in distinguishing between these potential causes and in guiding appropriate management decisions.

Laboratory Evaluation

Urinalysis

Performance of a urinalysis with microscopy is essential in the screening and monitoring of lupus nephritis.⁵⁵ Hematuria, pyuria, dysmorphic red blood cells, red blood cell casts,

and white blood cell casts may all be present. Red blood cell casts are very specific, but not sensitive, for the diagnosis of glomerulonephritis. Early morning urine specimens, which tend to be concentrated and acidic, are ideal for the detection of red blood cell casts. White blood cells, red blood cells, and white blood cell casts may indicate the presence of tubulointerstitial involvement. Hematuria in the absence of proteinuria might be due to urolithiasis, menstrual contamination, or bladder pathology, particularly transitional cell carcinoma in a patient with previous cyclophosphamide exposure.

Accurate measurement of proteinuria is critical because proteinuria is a very sensitive indicator of glomerular damage. In addition, studies of chronic kidney disease have shown that the magnitude of proteinuria is a strong predictor of glomerular filtration rate decline.⁵⁶ Normal daily protein excretion is less than 150 mg. Although the gold standard tool is an accurately collected 24-hour urine protein, this test can be cumbersome for patients and is prone to errors in undercollection and overcollection. Thus, many clinicians are currently using the random spot urine protein-to-creatinine ratio out of convenience. Use of the spot ratio is controversial because data suggest that the spot ratio often is not representative of the findings in a timed collection, especially in the range of 0.5 to 3.0 (the range of most lupus nephritis flares).⁵⁷ However, a spot ratio can be a helpful screening test for the presence of proteinuria and is useful in differentiating nephrotic from non-nephrotic range proteinuria.⁵⁸ Urine dipstick should not be used for the quantification of proteinuria because it reflects protein concentrations and varies depending on the volume of the sample. Many experts currently recommend calculation of the protein:creatinine ratio from a 12- or 24-hour urine collection as the gold standard of proteinuria assessment.⁵⁹

Measurement of Renal Function

Although easy to measure, serum creatinine is a fairly insensitive indicator of early decline in glomerular filtration rate (GFR). Creatinine is freely filtered across the glomerulus and is also secreted by the proximal tubule. As GFR falls, the rise in serum creatinine is counteracted by increased tubular creatinine secretion. In addition, hemodynamic changes such as those caused by treatment with angiotensin-converting enzyme inhibitors or nonsteroidal anti-inflammatory drugs are a common cause of changes in serum creatinine levels in the absence of progression of underlying renal disease. However, trending serum creatinine over time is a reasonable method by which to follow a patient's renal function. Some clinicians prefer to utilize equations that estimate GFR, such as the Cockcroft-Gault and Modification of Diet in Renal Disease (MDRD) study equations. Whichever method is chosen, the detection of changes in renal function over time is more important than the absolute level when following lupus nephritis patients in clinical practice.

Renal Biopsy

When an SLE patient has clinical or laboratory features that suggest the presence of nephritis, a renal biopsy should be

performed to confirm the diagnosis, evaluate the degree of disease activity, and determine an appropriate course of treatment.

Before renal biopsy, ultrasonography is recommended to assess kidney size and structure and to rule out renal vein thrombosis. Kidney size of less than 75% of normal is a relative contraindication to biopsy.⁶⁰ SLE glomerulonephritis is classified by the International Society of Nephrology/Renal Pathology Society (ISN/RPS) into six categories based on light microscopic, immunofluorescent, and electron micrographic findings⁶¹ (Table 80-4 and Figure 80-7).

An individual biopsy might exhibit just one of the ISN/RPS pathologic classes or a combination of classes. Class I is characterized by normal appearing glomeruli on light microscopy and mesangial immune deposits on immunofluorescence. Class II is characterized by mesangial proliferation on light microscopy and mesangial deposits on immunofluorescence. Class III and IV lupus nephritis lesions are highly inflammatory and are characterized by immune complex deposition in the subendothelial space. They have traditionally been described as “proliferative” because of the presence of proliferating endocapillary cells within the glomeruli. They are believed to be interrelated lesions that differ in the distribution of endocapillary immune complex deposition. Class III denotes that less than 50% of glomeruli are involved, and class IV denotes that 50% or more of glomeruli are involved. Class IV lesions are subcategorized according to whether most glomeruli show focal (<50% of the glomerular tuft) or global (≥50% of the glomerular tuft) involvement. These lesions are further described as active

(A), chronic (C), or a mixture of the two (A/C). Thick subendothelial immune deposits form classic “wire loop” lesions. Class V lupus nephritis is characterized by immune complex deposition in the subepithelial space, resulting in widespread thickened capillary loops. These findings are similar to those observed in idiopathic membranous nephritis. However, the presence of concomitant mesangial deposits plus or minus tubuloreticular inclusion bodies would favor the diagnosis of lupus. This lesion is commonly manifested clinically as nephrotic range proteinuria. Class V nephritis may occur in a pure histopathologic form or in combination with features of class III or class IV nephritis. Class VI nephritis is defined by the presence of more than 90% globally sclerotic glomeruli. In addition to the type of glomerular pathology, the ISN/RPS classification system dictates that tubulointerstitial disease and/or vascular disease should be noted on the diagnostic line.

Immunofluorescence studies are an important supplement to the findings on light microscopy. Immunofluorescence reveals the type and pattern of immune complex deposition. Lupus nephritis is characterized by a granular pattern of immunofluorescence along the glomerular basement membrane, mesangium, and/or tubular basement membranes. The characteristic findings of lupus nephritis are sometimes referred to as the “full-house” pattern, because IgG, IgM, IgA, C3, and C1q are all found in the deposits. Electron microscopy is useful in more precisely localizing the sites of immune complex deposition. The finding of tubuloreticular inclusion bodies within endothelial cells is strongly suggestive of the diagnosis of lupus nephritis. However, because tubuloreticular inclusion bodies are

Table 80-4 International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis

WHO Type	
Class I	Minimal Mesangial Lupus Nephritis Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence
Class II	Mesangial Proliferative Nephritis Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. Few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy
Class III	Focal Lupus Nephritis Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class IV	Diffuse Lupus Nephritis Active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is subdivided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits, but with little or no glomerular proliferation
Class V	Membranous Lupus Nephritis Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class V nephritis may occur in combination with class III or class IV, in which case both are diagnosed Class V nephritis may show advanced sclerotic lesions
Class VI	Advanced Sclerotic Lupus Nephritis ≥90% of glomeruli globally sclerosed without residual activity

WHO, World Health Organization.

Adapted from Weening JJ, et al: The classification of glomerulonephritis in systemic lupus erythematosus revisited, *J Am Soc Nephrol* 15:241, 2004.

Figure 80-7 A through D, World Health Organization types of lupus. (See Table 80-4 for a detailed description of histologic findings.) **A**, Normal glomerulus (type I). **B**, Mesangial proliferative (type II). **C**, Proliferative nephritis. Dramatic increase in mesangial and endocapillary cellularity produces a lobular appearance of the glomerular tufts and compromises the patency of most capillary loops. When less than 50% of glomeruli are involved, nephritis is denoted as focal (type III). When more than 50% of glomeruli are involved, nephritis is denoted as diffuse (type IV). **D**, Membranous nephropathy (type V). In membranous lupus nephropathy, the capillary walls of the glomerular tuft are prominent and widely patent, resembling “stiff” structures with decreased compliance. **E** through **H**, High-risk histologic features suggesting severe nephritis. **E**, Fibrinoid necrosis with karyorrhexis in a patient with focal proliferative glomerulonephritis. **F** and **G**, Cellular crescents with layers of proliferative endothelial cells and monocytes lining Bowman’s capsule along with a predominantly mononuclear interstitial infiltrate. **H**, Severe interstitial fibrosis and tubular atrophy. Note the thickening of the tubular basement membranes and tubular epithelial degeneration with separation of residual tubules caused by deposition of collagenous connective tissue among tubules.

associated with increased levels of interferon alpha, chronic viral infections such as hepatitis B/C and the human immunodeficiency virus (HIV) must be ruled out.

Renal biopsy is especially important because urinary parameters such as hematuria and the degree of proteinuria imperfectly predict the underlying renal pathology.^{62,63}

Hematuria might be absent in patients with severe class IV nephritis, and proteinuria can be modest in patients with class V nephritis. A repeat renal biopsy may be indicated in certain clinical settings (e.g., if a patient is not responding appropriately to therapy, if a patient unexpectedly worsens after having achieved a good response to therapy). Repeat

renal biopsy can be useful in detecting class transformation that occurs in 15% to 50% of lupus nephritis patients during the course of their disease. Class transformation can occur spontaneously or as a result of treatment.

Outcome

Each ISN/RPS histopathologic class portends a distinct renal prognosis. Patients with class I and class II nephritis have an excellent renal prognosis and do not require any specific therapy. In contrast, the long-term renal prognosis of class III or class IV nephritis is believed to be poor in the absence of immunosuppressive therapy. Although the long-term renal prognosis of class V nephritis is more favorable than that of class III or class IV nephritis, class V patients are more likely to suffer from morbid complications of the nephrotic syndrome, including cardiovascular disease, thromboembolic disease, and hyperlipidemia. Several epidemiologic studies have defined demographic, clinical, and histopathologic factors associated with renal outcome in patients with lupus nephritis. Studies have shown that African-Americans and Hispanics/Latinos generally experience a worse renal prognosis than white and Chinese populations. The reasons for this disparity most likely involve a combination of genetic and socioeconomic factors. A retrospective analysis of 65 patients at the NIH suggested that age greater than 30 years, African-American race, low hematocrit, elevated serum creatinine, and low C3 complement were associated with increased probability of renal failure. The histologic features of cellular crescents and interstitial fibrosis were also associated with worse renal prognosis.⁵⁰

PLEUROPULMONARY INVOLVEMENT

Pleuropulmonary manifestations of SLE are diverse and can involve any aspect of the lung (Table 80-5).

Pleuritis

Up to 50% of SLE patients will develop pleuritis. Clinically apparent pleural effusions are typically small, bilateral, and exudative.⁶⁴ Pleuritis is commonly manifested by pleuritic chest pain, but pleural effusions may be asymptomatic and detected on routine chest radiography performed for another purpose. Massive pleural effusions requiring pleurocentesis and/or pleurodesis are uncommon but have been reported.⁶⁵ The presence of pleuritis usually corresponds to active SLE in other organ systems.⁶⁶ Thoracoscopic evaluation has demonstrated nodules on the visceral pleura with immunoglobulin deposits detected on immunofluorescence. The differential diagnosis of pleural effusions in an SLE patient includes infection, malignancy, and heart failure. In addition, pleural effusions are a common feature of drug-induced lupus. In the absence of infection, high levels of serum C-reactive protein (CRP) have been found to correlate well with the presence of pleuritis and other forms of serositis in SLE.^{66,67} Thus, serum CRP may be a useful clue to the presence of pleuritis.

Lupus Pneumonitis

Acute lupus pneumonitis is a rare manifestation of SLE that presents as a severe, acute respiratory illness with fever, cough, pulmonary infiltrates, and hypoxemia. Chest radiography usually reveals bilateral, lower lobe, acinar infiltrates that often occur in conjunction with a pleural effusion. Histopathologic findings are nonspecific and include diffuse alveolar damage, inflammatory cell infiltrates, hyaline membranes, and alveolar hemorrhage.⁶⁸ Immunofluorescence studies have demonstrated granular deposits of IgG and C3 within the alveolar septa.⁶⁹ Because clinical and pathologic features of acute lupus pneumonitis are nonspecific, careful evaluation is critical to exclude other potential pulmonary processes such as infection. If routine blood and sputum cultures are nondiagnostic, bronchoscopy with

Table 80-5 Pleuropulmonary Manifestations of Systemic Lupus Erythematosus

Manifestation	Key Features
Pleuritis	May occur with or without effusion May correlate with elevated serum C-reactive protein
Pleural effusion	May be asymptomatic Usually small, bilateral, exudative Common feature of drug-induced lupus
Acute pneumonitis	Must exclude infection, malignancy, heart failure Severe respiratory illness with fever, cough, pulmonary infiltrates, hypoxemia Pleural effusion may be present High mortality rate
Chronic interstitial lung disease	Bronchoscopy with bronchoalveolar lavage might be necessary to exclude infection May develop after acute pneumonitis or in a more insidious fashion Presents as dyspnea on exertion, pleuritic chest pain, nonproductive cough High-resolution computed tomography more sensitive than chest x-ray in detecting disease Must exclude infection, pulmonary edema, malignancy
Diffuse alveolar hemorrhage	Presents as dyspnea and cough, alveolar infiltrates, fall in blood hemoglobin level Hemoptysis may not be present Diffusion capacity of carbon monoxide typically increased Bronchoscopy with bronchoalveolar lavage confirms the diagnosis and excludes infection
Pulmonary arterial hypertension	High mortality rate Presents as dyspnea on exertion, fatigue, chest pain, nonproductive cough Diagnosis should be confirmed with right heart catheterization
Shrinking lung syndrome	Exclude secondary causes of pulmonary hypertension, including thromboembolic disease Dyspnea, low lung volumes, elevation of hemi-diaphragms in absence of lung parenchymal involvement

bronchoalveolar lavage can be useful in detecting pulmonary pathogens. A “tree and bud” pattern on high-resolution computed tomography (HRCT) may suggest the presence of an atypical pneumonia. Acute lupus pneumonitis is associated with significant morbidity and mortality. One series of 12 patients reported a mortality rate of 50% with deaths from respiratory failure, opportunistic infection, and thromboembolic events. Three of the surviving patients progressed to chronic interstitial pneumonitis.⁷⁰

Chronic Interstitial Lung Disease

Chronic interstitial lung disease is a rare manifestation of SLE. It occurs more commonly in other connective tissue diseases such as systemic sclerosis, rheumatoid arthritis, and polymyositis/dermatomyositis. Interstitial lung disease in the setting of SLE can develop after one or more episodes of acute pneumonitis but can also occur in an insidious fashion.⁷⁰ Symptoms are similar to those seen in patients with idiopathic interstitial lung disease and include dyspnea on exertion, pleuritic chest pain, and chronic, nonproductive cough. The diagnosis of interstitial lung disease is often made on the basis of clinical-radiologic findings; lung biopsy is not routinely performed. Chest radiography might be normal early in the disease but can show reticular opacities. Pulmonary function studies show a restrictive pattern with reduction in total lung capacity and reduction in the diffusion capacity of carbon monoxide (DLCO). HRCT is more sensitive than chest radiography in detecting interstitial lung disease and in distinguishing reversible lesions (ground glass opacities) from irreversible fibrotic lesions. Nonspecific interstitial pneumonia (NSIP) and usual interstitial pneumonia (UIP) are the most common patterns detected on histopathology and HRCT. Before making the diagnosis of interstitial lung disease, it is important to exclude infection, pulmonary edema, and malignancy.

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) is a life-threatening manifestation of SLE that occurs in less than 2% of patients. It is characterized by acute or subacute onset of dyspnea and cough in the setting of new alveolar infiltrates on chest radiography and a fall in blood hemoglobin level. Similar to other causes of DAH, hemoptysis is not universally present. Although most patients are too ill to receive this test, the DLCO is typically increased in the setting of DAH owing to the presence of extravascular hemoglobin within the alveoli. Bronchoscopy with bronchoalveolar lavage (BAL) is important in ruling out infection and confirming the diagnosis. Characteristic findings include visualization of blood in the airways and serosanguineous BAL fluid that does not clear with continued lavage. Hemosiderin-laden macrophages may be seen in the BAL fluid. Various histopathologic patterns have been described in lupus DAH, including bland pulmonary hemorrhage, capillaritis, diffuse alveolar damage, and vasculitis of small arterioles and small muscular pulmonary arteries. DAH usually occurs in the setting of serologically and clinically active SLE, and lupus nephritis is the most common concurrent SLE manifestation. However, DAH occasionally may be the initial manifestation of SLE. Mechanical ventilation is often required,⁷¹

and infectious complications are common. Despite aggressive therapy, mortality from DAH continues to be 50%.

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) is a rare, devastating complication of SLE that is defined as a mean pulmonary artery pressure greater than 25 mm Hg at rest on right heart catheterization. Other key findings on heart catheterization include a normal pulmonary capillary wedge pressure and elevated pulmonary capillary resistance. Symptoms of PAH include dyspnea on exertion, fatigue, chest pain, and nonproductive cough. Physical examination findings may include a pronounced second pulmonary heart sound, a left parasternal lift, and signs of a volume-overloaded state. Chest radiography and HRCT are important in excluding lupus pneumonitis. Chest radiography may show cardiomegaly and a prominent pulmonary artery segment. The electrocardiogram often shows right axis deviation. Pulmonary function studies demonstrate a reduction in DLCO. Although transthoracic Doppler echocardiography is a decent screening test for PAH, the diagnosis should be confirmed by right heart catheterization. Similar to interstitial lung disease, PAH more commonly occurs in association with scleroderma and mixed connective tissue disease.

In an SLE patient who has been diagnosed with PAH, an evaluation must be performed for secondary causes of pulmonary hypertension. Ventilation and perfusion (V/Q) lung scan and/or helical computed tomography are useful in excluding chronic thromboembolic disease. Echocardiography can rule out left heart failure and intracardiac shunting. A sleep study can be useful in ruling out obstructive sleep apnea. An evaluation for interstitial lung disease is necessary. Some studies suggest that PAH occurs more commonly in patients with Raynaud's phenomenon.

Other

Shrinking lung syndrome occurs in a small subset of SLE patients and should be considered when evaluating an SLE patient with unexplained dyspnea and pleuritic chest pain.^{72,73} The cause of the disorder remains controversial. Diaphragmatic myopathy, abnormal chest wall expansion, phrenic neuropathy, and pleural inflammation/fibrosis have been reported as possible factors. The prognosis of this syndrome seems to be good, and progressive respiratory failure is uncommon.

Although symptomatic bronchiolar disease is uncommon in SLE, abnormalities in pulmonary function studies have been reported in up to two-thirds of SLE patients.⁷⁴ One study of nonsmoking SLE patients found that 24% of patients had pulmonary function studies consistent with small airway disease. Rare case reports of bronchiolitis obliterans organizing pneumonia (BOOP) in the setting of SLE have been described.⁷⁵

CARDIOVASCULAR INVOLVEMENT

Cardiovascular disease is a frequent complication of SLE and may involve the pericardium, myocardium, valves, and coronary arteries.

Pericarditis

Pericarditis, with or without an effusion, is the most common cardiac manifestation of SLE, occurring in more than 50% of SLE patients at some point during the course of their disease.⁷⁶ Pericardial effusions are usually small and asymptomatic and typically are detected on echocardiography performed for another indication. Consistent with this observation, necropsy studies have shown that histopathologic evidence of pericarditis is much more common than clinically symptomatic disease during life.⁷⁷ Symptomatic pericarditis classically presents as sharp, precordial chest pain that is improved in the upright position. A pericardial rub and tachycardia may be detected on cardiac auscultation. The electrocardiogram demonstrates diffuse ST segment elevation. Similar to pleuritis, pericarditis usually occurs in the setting of active SLE in other organ systems. Although rare, SLE pericarditis complicated by large effusions and tamponade physiology have been reported. Purulent effusions necessitating pericardiocentesis have also been described, but rarely. The differential diagnosis of precordial chest pain in an SLE patient includes costochondritis, gastroesophageal reflux disease, pulmonary embolism, myocardial ischemia, pleuritis, pneumonitis, and pulmonary hypertension.

Myocarditis

Myocarditis, an uncommon manifestation of SLE, should be suspected in a patient presenting with various combinations of the following clinical features: unexplained heart failure or cardiomegaly, unexplained tachycardia, and unexplained electrocardiographic abnormalities. Echocardiography can confirm the presence of systolic or diastolic dysfunction and/or global hypokinesis. If myocarditis is suspected, an endomyocardial biopsy may be helpful in confirming the diagnosis and excluding other causes of cardiomyopathy such as hydroxychloroquine toxicity. The distinguishing pathologic finding of hydroxychloroquine toxicity is myocyte vacuolization in the absence of active myocarditis. Histopathologic findings of SLE myocarditis include perivascular and interstitial mononuclear cell infiltration and sometimes fibrosis and scar.⁷⁷

Valvular Abnormalities

Several valvular abnormalities have been described in patients with SLE, including Libman-Sacks endocarditis (also known as atypical verrucous endocarditis), valvular thickening, valvular regurgitation, and valvular stenosis. One transesophageal echocardiographic (TEE) study demonstrated a prevalence of valvular abnormalities of 61% in SLE patients compared with 9% of controls, with vegetations present in 43% of SLE patients compared with none of the controls.⁷⁸ Valvular thickening with a predilection for the mitral and aortic valves was the most common abnormality, occurring in 50% of SLE patients. Valvular regurgitation and stenosis were detected in 25% and 4% of patients, respectively.⁷⁸ In this study, the presence and progression of valvular disease were not associated with SLE disease activity or treatment. Over a follow-up period of up to 5 years, some valvular abnormalities resolved and some

new lesions occurred. The combined incidence of stroke, peripheral embolism, congestive heart failure, infective endocarditis, need for valve replacement, and death was 22% among patients with valvular disease compared with 15% in those without valvular disease.⁷⁸

Libman-Sacks endocarditis has been recognized in multiple pathologic studies as a characteristic valvular abnormality in SLE. Libman-Sacks verrucae typically appear as pea-sized, flat or raised, granular lesions that occur most commonly on the ventricular aspects of the mitral valve posterior leaflet.⁷⁷ The verrucae often extend onto the adjacent left ventricular mural endocardium and may lead to adherence of the leaflet and chordae tendineae to the ventricular mural endocardium, resulting in valvular regurgitation. All four valves may be involved, but recent studies suggest a predominance of left-sided lesions. The lesions are frequently clinically silent because they are typically found on the undersurface of valve leaflets, surrounded by fibrous tissue. Histologically, two types of verrucae have been described: (1) active lesions consisting of fibrin clumps with infiltrating lymphocytes and plasma cells, and (2) healed lesions consisting of dense vascularized fibrous tissue with or without calcification.⁷⁷ Combinations of active and healed lesions also occur. Verrucae typically do not contain polymorphonuclear cells; thus, the presence of such cells should prompt consideration of infectious endocarditis. Immunopathologic studies have demonstrated immunoglobulin and complement deposition in a granular pattern at the base of the valve, along the valve leaflet, and within the verruca itself.⁷⁹ Cardiac murmurs are frequently heard in patients with SLE. They may simply result from high-flow states such as fever and anemia, or they may reflect cardiac pathology such as mitral valve prolapse or infective endocarditis. When a new murmur is evaluated, a transthoracic echocardiogram (TTE) is an appropriate first test. However, TEE should be utilized in the event of a nondiagnostic TTE or in a patient with suspected thromboembolic events. TEE has been shown to be superior to TTE for detection of Libman-Sacks endocarditis.⁸⁰ Although thromboembolic events are believed to be rare complications of Libman-Sacks endocarditis, one study showed that valvular heart disease detected on TTE was associated with the presence of cerebral infarcts on MRI.⁸¹ It remains uncertain whether the incidence of valvular disease is increased in SLE patients who also have circulating antiphospholipid antibodies.

Coronary Artery Disease

Both intramural and extramural coronary artery disease is increased in patients with SLE. Necropsy studies have demonstrated fibrous intimal proliferation of small intramural coronary arteries and obstruction of these arteries with hyaline material.⁷⁷ These lesions are similar to those observed in pathologic studies of renal and central nervous system tissue in SLE patients. The large epicardial coronary arteries may be obstructed owing to arterial emboli, in situ thrombosis, vasculitis, or atherosclerotic disease. True coronary artery vasculitis is exceedingly rare. In contrast, atherosclerotic disease is a well-recognized complication of long-standing SLE.⁸² Autopsy studies have demonstrated atherosclerosis in 25% to 40% of SLE patients.^{77,83} One epidemiologic study demonstrated that young women with

SLE have a 50-fold higher risk of myocardial infarction compared with age-matched controls.⁸⁴ A multicenter inception cohort determined that male sex and older age at SLE diagnosis were significantly associated with the presence of atherosclerotic disease.⁸⁵ Although patients with SLE are more likely to have classic atherosclerotic risk factors such as hypertension and exposure to corticosteroids, these risk factors alone do not fully account for the increased risk of atherosclerosis seen in SLE patients.⁸⁶ Thus, SLE itself is believed to be an independent risk factor.

The possibility of coronary artery disease must be considered in any SLE patient presenting with chest pain and/or shortness of breath, and one should have a low threshold for a functional evaluation with a cardiac stress test. Cardiac catheterization might also be necessary for diagnosis and therapeutic intervention. It is important to evaluate these patients for the presence of antiphospholipid antibodies because coronary artery thrombosis may be a manifestation of the antiphospholipid antibody syndrome. Evaluation for and treatment of modifiable risk factors such as obesity, smoking, hypertension, and hyperlipidemia are important in mitigating the development and progression of atherosclerotic disease.

NEUROPSYCHIATRIC INVOLVEMENT

General Considerations

Neuropsychiatric lupus (NPSLE) consists of a broad range of neurologic and psychiatric manifestations that can involve any aspect of the central or peripheral nervous system. With the intention of improving the terminology and classification of NPSLE, an American College of Rheumatology (ACR) subcommittee categorized NPSLE into 19 distinct syndromes encompassing the central (CNS) and peripheral (PNS) nervous system⁸⁷ (Table 80-6). The extent of this classification system underscores the complexity of NPSLE. CNS disorders range from diffuse processes such as acute confusional state, headache, psychosis, and mood disorders to more focal processes such as seizures, myelopathy, and chorea. It is notable that the ACR classification system has removed the cryptic term “lupus cerebritis” from the vernacular. Although the ACR case definitions are very helpful in providing a framework in which to think about

and study NPSLE, accurate attribution of neuropsychiatric manifestations remains challenging. It is often difficult to distinguish whether neuropsychiatric symptoms are due to active SLE or to other factors such as infection, metabolic abnormalities, severe hypertension, adverse effects of medications, or independent neurologic or psychiatric problems. No laboratory or imaging study is sufficiently sensitive or specific to confirm the diagnosis of neuropsychiatric SLE. Instead, the diagnosis is based on a thorough clinical evaluation that is corroborated by findings (or lack thereof) on brain imaging, serologic testing, lumbar puncture, and neuropsychiatric assessment.

Pathogenesis

Multiple pathogenic mechanisms are undoubtedly involved in the various NPSLE syndromes, but in most cases the precise pathogenesis is unknown. Many of the manifestations can be grouped into two broad categories: primary vascular injury and primary inflammatory injury. A combination of the two categories can also occur. Vascular injury includes damage to both large and small vessels via thromboembolic events, often as a consequence of antiphospholipid syndrome. In some patients, vasculopathy of small vessels may be due to vascular hyalinization, perivascular inflammation, and endothelial proliferation. In contrast, inflammatory-mediated injury might result from increased permeability of the blood-brain barrier, intrathecal production of inflammatory cytokines, and damage from antineuronal antibodies. Histopathologic studies have demonstrated multiple CNS abnormalities, including large and small multifocal infarctions, hemorrhage, bland small vessel vasculopathy, cortical atrophy, brain edema, and demyelination. True vasculitis of cerebral vessels is rare. Several autoantibodies have been implicated in the pathogenesis of some neuropsychiatric manifestations, particularly psychosis, but they lack sufficient sensitivity or specificity to guide diagnosis.⁸⁸

Approach to Diagnosis

The diagnostic evaluation of a patient with potential NPSLE is tailored to the presenting neuropsychiatric manifestation. Depending on the manifestation, consultation with a neurologist and/or a psychiatrist is advised. The most important first step is exclusion of an alternative explanation for the neuropsychiatric symptoms/signs. Lumbar puncture with cerebrospinal fluid (CSF) examination is useful for exclusion of an infectious origin. Mild lymphocytic pleocytosis and elevated CSF protein are sometimes observed but are not uniformly present. CSF findings are not sensitive or specific enough to confirm a diagnosis of neuropsychiatric SLE. It is important to recognize that infection is a common cause of CNS symptoms in SLE patients who are hospitalized with altered mental status,⁸⁹ and must be rigorously ruled out. Progressive multifocal leukoencephalopathy (PML) is a rare infection that also merits consideration in an SLE patient presenting with symptoms of CNS dysfunction. PML occurs more frequently in SLE patients than in patients with other rheumatic diseases, even in the absence of significant immunosuppressive therapy.⁹⁰ Thus, in an SLE patient with unexplained new

Table 80-6 American College of Rheumatology Classification of Neuropsychiatric Syndromes in Systemic Lupus Erythematosus

Central Nervous System	Peripheral Nervous System
Aseptic meningitis	Guillain-Barré syndrome
Cerebrovascular disease	Autonomic disorder
Demyelinating syndrome	Mononeuropathy, single/multiplex
Headache	Myasthenia gravis
Movement disorder	Cranial neuropathy
Myelopathy	Plexopathy
Seizure	Polyneuropathy
Acute confusional state	
Anxiety disorder	
Cognitive dysfunction	
Mood disorder	
Psychosis	

neurologic symptoms, polymerase chain reaction (PCR) of the CSF for the presence of John Cunningham (JC) virus should be considered. In situations where PCR is negative, brain biopsy might be needed to confirm the diagnosis. Electromyography and nerve conduction studies are important in the setting of suspected peripheral neuropathy. Electroencephalogram (EEG) is necessary in the evaluation of seizure. Neuropsychological testing may be helpful in the setting of suspected cognitive dysfunction.

MRI is the preferred imaging modality in patients with suspected NPSLE. The most common noted abnormalities are small, hyperintense, T2-weighted, focal white matter lesions located in the periventricular and subcortical white matter of the frontoparietal region of the brain. However, these findings are nonspecific and can be observed in other disease processes such as atherosclerotic vascular disease and multiple sclerosis. Other common MRI findings include cortical atrophy, ventricular dilation, cerebral edema, diffuse white matter abnormalities, focal atrophy, infarction, leukoencephalopathy, and hemorrhage.⁹¹ MRI is especially useful in detecting the presence of infarcts, hemorrhage, and myelopathy and sometimes can help to exclude infectious conditions such as brain abscess.⁹¹ MRI is most likely to show abnormalities in the setting of focal neurologic deficits, seizures, chronic cognitive dysfunction, and antiphospholipid antibody-mediated disease and is less likely to show abnormalities in the setting of headache, acute confusional state, and psychiatric syndromes.

Estimates of the prevalence of NPSLE have varied widely in the literature, largely depending on the extent to which headache and/or mild cognitive abnormalities have been included in the analysis. However, the preponderance of these studies suggests that CNS manifestations predominate over PNS manifestations. Several of the more common syndromes and associated differential diagnoses are described in the following paragraphs.

Selected Neuropsychiatric Lupus Syndromes

Headaches are reported in more than 50% of SLE patients, but attribution of the headache to SLE is extremely difficult. Both migrainous and tension-type headaches have been described. One meta-analysis⁹² determined that the prevalence of primary headache syndromes was not different between SLE and control patients, and that headache was not related to SLE disease activity. The evaluation of headache in an SLE patient should be similar to that in a non-SLE patient and should be directed by the presence or absence of worrisome features such as fever, meningismus, altered mental status, and focal neurologic signs.

Cognitive dysfunction, manifested primarily by deficits in thinking, memory, and concentration, is being increasingly recognized in SLE patients. Some have estimated a prevalence of up to 80%, although serious cognitive impairment is much less common. Some studies suggest that cognitive dysfunction may be associated with the presence of antiphospholipid antibodies, but a causal relationship has not been definitively established. Documentation of the presence and extent of cognitive dysfunction via neuropsychiatric testing can be useful in establishing a baseline in a particular patient that can be followed over time, particularly when a therapeutic intervention is being considered.

Psychiatric disorders such as psychosis, depression, and anxiety can occur in SLE, and consultation with a psychiatrist is highly recommended in the evaluation of patients with these symptoms. An SLE patient presenting with psychosis represents a distinct diagnostic and therapeutic challenge. The differential diagnosis includes CNS infection, primary schizophrenia, systemic metabolic abnormalities, and psychosis occurring as a side effect of corticosteroid therapy or illicit drugs. Steroid-induced psychosis is dose dependent and typically occurs within the first 2 weeks of treatment initiation.

Although rare, demyelinating syndromes such as optic neuritis and myelitis can occur as part of the spectrum of NPSLE. Optic neuritis is characterized by pain with eye movement, central visual field loss, and a waxing and waning course.⁹³ Optic neuritis should be differentiated from ischemic optic neuropathy, which typically presents with acute, painless loss of vision and lack of significant improvement in vision over time.⁹⁴ Myelitis is characterized by the onset of bilateral lower extremity paresthesia, numbness, and weakness that can rapidly progress to involve the upper limbs and the muscles of respiration. A sensory level is usually noted, and autonomic involvement of the bowel and bladder is common. Band-like pain or discomfort around the abdomen is a characteristic symptom. It is important to differentiate myelitis from other causes of myelopathy, including infection, structural spinal cord abnormalities, and vascular insult to the spinal cord. Spinal cord MRI is the critical first test. CSF examination is important to rule out infection.

The combination of optic neuritis and myelitis presents a special clinical challenge because this combination of features can occur in the setting of SLE, multiple sclerosis (MS), or neuromyelitis optica (NMO).⁹⁵ Complicating matters, the clinical presentation of antiphospholipid antibody syndrome can mimic demyelinating disease. A thorough clinical history, MRI, CSF analysis, and serologic testing are helpful in distinguishing these entities. NPSLE and MS can have identical white matter lesions on brain MRI. Spinal cord lesions may differ in that MS spinal cord lesions usually span an area measuring less than two spinal segments, but SLE lesions are often longitudinally extensive with involvement of more than three spinal cord segments. Although oligoclonal bands may be present in the CSF of both SLE and MS patients, the absence of oligoclonal bands and the presence of a pleocytosis significantly lessen the likelihood of MS. Although a positive ANA has been described in up to 27% of patients with MS,⁹⁵ more specific subserologies such as anti-dsDNA and anti-Sm favor the diagnosis of SLE. NMO is defined as manifested by two of the following three features: presence of the NMO IgG antibody (antibody to aquaporin 4), absence of brain lesions diagnostic of MS, and longitudinally extensive myelitis on MRI.⁹⁶ The NMO antibody has a specificity of greater than 90% for the diagnosis of NMO. However, SLE and NMO may occur concurrently in a given patient.

Patients with SLE are at increased risk of stroke, with ischemic stroke being more common than intracerebral hemorrhage.⁹⁷ Studies have demonstrated an association between the presence of antiphospholipid antibodies (aPL) and/or valvular heart disease and the risk of stroke.⁸¹ Brain MRI is a critical test in the diagnosis of ischemic or

hemorrhagic stroke, and magnetic resonance angiography (MRA) can detect vessel aneurysms. Echocardiography, carotid ultrasound, and electrocardiography are important diagnostic tests in the setting of suspected thromboembolic cerebrovascular disease.

Peripheral neuropathy has been observed in up to 20% of SLE patients and typically is characterized by a symmetric, length-dependent sensory or sensorimotor polyneuropathy. Vasculitis of the vasa nervorum and demyelination are two well-recognized pathogenic mechanisms. When the results of nerve conduction studies (NCS) are normal, small-diameter nerve fibers are likely involved. Small-fiber involvement frequently presents as fluctuating numbness and tingling of the upper extremities and hands. A devastating, large-fiber vasculitic neuropathy can also develop in patients with SLE. Autonomic neuropathies, cranial neuropathies, and abnormalities of the neuromuscular junction resembling myasthenia gravis have also been described.

GASTROINTESTINAL INVOLVEMENT

SLE can involve any part of the gastrointestinal system. Dysphagia is noted in up to 13% of patients, and manometric studies have detected abnormalities of esophageal motility.⁹⁸ Decreased peristalsis is most commonly observed in the upper one-third of the esophagus. In contrast to scleroderma, involvement of the lower esophageal sphincter is rare in SLE.⁹⁹ A variety of potential pathogenic mechanisms have been described, including muscle atrophy, inflammation of esophageal muscle, and ischemic or vasculitic damage to the Auerbach plexus.

Abdominal pain, sometimes accompanied by nausea and vomiting, has been reported in up to 40% of SLE patients and can be due to SLE-related causes, medication side effects, and non-SLE-related causes such as infection.⁹⁸ When evaluating an SLE patient with abdominal pain, it is critical to rule out non-SLE conditions. It is important to note that when patients are treated with corticosteroids and/or other immunosuppressives, clinical signs of an acute abdomen such as rebound tenderness can be masked. Thus, delay in diagnosis is common. SLE-related causes of abdominal pain may include peritonitis, pancreatitis, mesenteric vasculitis, and intestinal pseudo-obstruction. Although autopsy studies have revealed evidence of peritoneal inflammation in up to 72% of SLE patients,¹⁰⁰ the presence of ascites is rare. If an SLE patient presents with abdominal pain and ascites, paracentesis is warranted to rule out infection. Peritonitis can also occur in the setting of mesenteric ischemia, bowel infarction, and pancreatitis. Thus, abdominal imaging is an important part of the initial evaluation.

Pancreatitis due to SLE is uncommon and usually is associated with active SLE in other organs. When considering the possible diagnosis of pancreatitis, it is important to note that elevated serum amylase may be misleading in that it has been observed in SLE patients in the absence of pancreatitis.¹⁰¹ Although corticosteroids and azathioprine have been associated with the development of pancreatitis in non-SLE patients, these medications do not seem to play a major role in the development of pancreatitis in SLE patients.¹⁰² It is important to rule out non-SLE causes of pancreatitis such as biliary disease, alcohol consumption, and hypertriglyceridemia.

Mesenteric vasculitis is a very rare manifestation of SLE that can present with a range of symptoms from cramping, bloating, and anorexia to an acute abdomen with diarrhea and gastrointestinal hemorrhage. Accurate diagnosis and prompt treatment are essential to prevent the potential catastrophic complications of necrotic bowel, perforation, and sepsis. Abdominal radiography may show distention of bowel loops, thickening and thumbprinting of the bowel wall, and/or free air in the abdomen. Ultrasonography may be useful in demonstrating bowel wall edema and thickening. Abdominal CT is thought to be the most useful imaging modality for the early diagnosis of mesenteric ischemia and can demonstrate prominence of mesenteric vessels with a palisade pattern supplying dilated bowel loops, ascites, and bowel wall thickening with a double halo sign.¹⁰³ Gastroscopy and colonoscopy can sometimes reveal findings of ischemia and ulceration. Because lupus mesenteric vasculitis typically involves the small vessels (arterioles and venules) of the bowel submucosa, mesenteric angiography is usually nondiagnostic. However, angiography can be helpful in ruling out larger vessel causes of mesenteric ischemia, such as polyarteritis nodosa, atherosclerotic disease, or thrombosis resulting from antiphospholipid antibody disease.

Liver test abnormalities have been described in up to 60% of SLE patients at some point during the course of their illness, but clinically significant liver disease is rarely a direct manifestation of SLE.¹⁰⁴ For this reason, the presence of liver disease should prompt a search for non-SLE causes, including medications such as nonsteroidal anti-inflammatory drugs, methotrexate, and azathioprine. Abnormal liver enzymes may be caused by hepatic steatosis as a result of obesity, concomitant diabetes mellitus, or treatment with corticosteroids. Infections such as viral hepatitis, cytomegalovirus (CMV), and Epstein-Barr virus (EBV) must also be excluded. Once medications and infections have been ruled out as possible culprits, persistent liver test abnormalities should prompt an investigation with an abdominal ultrasound and possibly a liver biopsy. Lupus hepatitis is believed to be a distinct entity from autoimmune hepatitis.¹⁰⁵ Lupus hepatitis is typically characterized by the presence of lobular inflammation with a paucity of lymphoid infiltrates. These findings contrast with those of autoimmune hepatitis, in which periportal (interface) inflammation and dense lymphoid infiltrates dominate. Although ANA is frequently seen in these disorders, anti-smooth muscle and anti-LKM antibodies are more frequently noted in autoimmune hepatitis than in lupus hepatitis. Rarely, nodular regenerative hyperplasia complicates SLE. This disorder causes diffuse nodularity of the liver with little fibrosis and can result in portal hypertension. Nodular regenerative hyperplasia is also associated with the presence of antiphospholipid antibodies in some patients.¹⁰⁶ Vascular disorders of the liver such as Budd-Chiari syndrome, hepatic veno-occlusive disease, and hepatic infarction have been described, especially in the setting of antiphospholipid antibodies.

Other rare gastrointestinal manifestations of SLE include intestinal pseudo-obstruction and protein-losing enteropathy. Intestinal pseudo-obstruction is characterized by decreased intestinal motility caused by dysfunction of the visceral smooth muscle or enteric nervous system.¹⁰⁷ The

small bowel is more frequently involved than the large bowel. Presenting symptoms include abdominal pain, nausea, vomiting, and abdominal distention. Patients with protein-losing enteropathy experience abdominal pain, profound pitting edema, and diarrhea and are noted to have a hypoalbuminemia. Other causes of hypoalbuminemia, such as nephrotic syndrome from renal disease, must be excluded.

OPHTHALMOLOGIC

SLE can affect the eye in a variety of ways. The most common ocular manifestation is keratoconjunctivitis sicca (KCS), which can occur in the presence or absence of secondary Sjögren's syndrome.¹⁰⁸ Retinal abnormalities can be detected on ophthalmoscopic examination as retinal hemorrhages, vasculitic-appearing lesions, cotton wool spots, and hard exudates. SLE retinopathy is believed to be an immune complex-mediated vasculopathy and/or the result of microthrombotic events. The presence of retinal abnormalities has been shown to correlate with lupus nephritis, CNS lupus, and the presence of antiphospholipid antibodies.¹⁰⁹ Episcleritis and scleritis can occur in SLE. Uveitis is extremely rare. Discoid lupus can involve the lower eyelid and conjunctiva. Glucocorticoids and antimalarial agents, two medications commonly used for the treatment of SLE, can affect the eye. Posterior subcapsular cataracts and elevated intraocular pressure are well-described complications of glucocorticoid therapy, and maculopathy is a rare but serious complication of the use of hydroxychloroquine and chloroquine. The risk of retinal toxicity is low if the daily dose of chloroquine is kept below 3 mg/kg of ideal body weight and the daily dose of hydroxychloroquine is kept at or below 6.5 mg/kg of ideal body weight.

HEMATOLOGIC

Hematologic involvement is common in SLE; all three blood cell lines can be affected. When evaluating a patient with the hematologic abnormalities as described later, it is always necessary to consider the potential of myelosuppression from medications such as methotrexate, azathioprine, mycophenolate mofetil, and cyclophosphamide. In addition, corticosteroids are a common cause of lymphopenia and leukocytosis secondary to neutrophilia.

Anemia

Anemia of chronic disease (ACD) is the most common anemia in SLE. It is a normochromic, normocytic anemia characterized by the presence of low serum iron, low transferrin, and normal to increased serum ferritin. ACD can coexist with anemias resulting from other processes. Auto-immune hemolytic anemia (AIHA) should be suspected in the setting of the following laboratory abnormalities: increased serum unconjugated bilirubin, increased lactate dehydrogenase (LDH), increased reticulocyte count, and reduced serum haptoglobin. The direct Coombs' test is typically positive and usually is mediated by warm-reacting IgG anti-erythrocyte antibodies. The peripheral blood smear demonstrates spherocytosis. Some reports have suggested an association between AIHA and the presence of anticardiolipin antibodies.^{110,111} A positive direct Coombs' test can

occur without hemolysis. AIHA may be the presenting manifestation of SLE, or it may predate full-blown SLE by many years.

Microangiopathic hemolytic anemia (MAHA), characterized by the presence of schistocytes on peripheral blood smear, should prompt consideration of thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS). TTP is a syndrome consisting of MAHA, thrombocytopenia, fever, neurologic symptoms, and renal involvement, and may be associated with SLE. Because MAHA, thrombocytopenia, neurologic symptoms, and renal involvement can also occur in catastrophic antiphospholipid antibody syndrome (CAPS), antiphospholipid antibodies should always be measured as part of the evaluation. Blood loss, renal insufficiency, pure red cell aplasia, and medication-induced myelotoxicity are additional potential causes of anemia in SLE patients.

Leukopenia

Leukopenia occurs in approximately 50% of SLE patients and can occur secondary to lymphopenia and/or neutropenia. One study of 158 newly diagnosed, clinically active SLE patients demonstrated that 75% of patients had lymphocyte counts lower than 1500 cells/ μ L, and that lymphopenia eventually developed in 93% of patients.¹¹² The presence of lymphocytotoxic antibodies in some SLE patients correlates with lymphopenia and with disease exacerbation.¹¹³ Lymphopenia may be a side effect of treatment with glucocorticoids or other immunosuppressive agents. Neutropenia due to SLE can result from immune-mediated destruction or marrow suppression.

Thrombocytopenia

Mild thrombocytopenia is noted in up to 50% of SLE patients, but severe thrombocytopenia can also occur. Thrombocytopenia can be the result of immune-mediated platelet destruction similar to immune thrombocytopenic purpura (ITP). The platelet IIb/IIIa antigen is the primary target. Thrombocytopenia can also be caused by a consumptive process such as TTP or splenomegaly. Antithrombopoietin antibodies have been found in the sera of some SLE patients and have been correlated with lower platelet counts.¹¹⁴ Chronic, low-level thrombocytopenia is a characteristic feature of the antiphospholipid antibody syndrome. Similar to AIHA, isolated ITP may pre-date the development of complete SLE by several years.¹¹⁵

LYMPHADENOPATHY AND SPLENOMEGALY

Lymphadenopathy commonly occurs in association with active SLE and is characterized by the presence of enlarged, soft, nontender lymph nodes. Lymphadenopathy can be focal or generalized; the cervical, axillary, and inguinal regions are typically involved. Lymph node histopathology demonstrates reactive hyperplasia and varying degrees of coagulative necrosis. The presence of hematoxylin bodies is specific for SLE. Histologic features of Castleman's disease have been reported.¹¹⁶ The differential diagnosis of lymphadenopathy in an SLE patient includes infection and/or a

lymphoproliferative process; lymph node biopsy is sometimes required for diagnosis. Splenomegaly can be observed in patients with SLE and may be associated with hepatomegaly. Histopathologic studies demonstrate periarterial fibrosis (onion-skin lesions). Splenic atrophy and functional asplenism have also been reported.¹¹⁷

DIAGNOSIS

Establishing the diagnosis of SLE can be challenging because of its heterogeneous disease manifestations and waxing and waning clinical course. No clinical manifestation or laboratory test can serve as a definitive diagnostic test. Instead, SLE is diagnosed on the basis of a constellation of characteristic symptoms, signs, and laboratory findings in the appropriate clinical context. Although the ACR classification criteria (see Table 80-1) cannot always be relied upon for diagnostic purposes in individual patients, they serve as useful reminders of the wide variety of clinical features that can be seen in SLE.

Serologic Tests

Serologic tests play an important role in the diagnosis of SLE. SLE is the prototypic systemic humoral autoimmune disease. As such, it is characterized by production of a wide variety of autoantibodies, which often provide important diagnostic information¹¹⁸ (Table 80-7). The hallmark serologic feature is the presence of ANAs, as reflected by a positive ANA test. The gold standard method for detecting ANA is indirect immunofluorescence using a human epithelial cell tumor line (HEp2 cell line). With this method, the ANA test is highly sensitive in that it is positive in more than 95% of people with SLE. Because of a desire for automation and cost savings, some laboratories are utilizing the enzyme-linked immunosorbent assay (ELISA) as the method of testing for ANA. However, the ELISA method is less accurate than the immunofluorescence method, resulting in a higher false-negative rate. Positive ANA tests also occur in many other autoimmune diseases, including rheumatoid arthritis, scleroderma, polymyositis, and autoimmune thyroiditis, among others. ANAs are also detectable in low titers (<1:80) in many people without autoimmune disease, especially in the elderly.¹¹⁹ Therefore, a positive test is not sufficient to establish the diagnosis of SLE. On the other hand, a negative test can be helpful in

ruling out SLE. Although “ANA-negative” SLE has been reported, it is very rare with the immunofluorescence method of testing. In those rare instances, other tests (e.g., anti-Ro/SSA) confirm the presence of lupus-associated autoantibodies.¹²⁰

Once it has been established that ANAs are present, it is important to determine which particular nuclear antigens may be the target of the autoantibodies, because some of these antigen-specific responses provide great diagnostic specificity. The most important of these tests is the test for antibodies to double-stranded DNA (anti-dsDNA). Anti-dsDNA antibodies are present in no more than 50% to 60% of patients with lupus, so their absence does not exclude the possibility of SLE. However, the presence of these antibodies is highly specific for SLE and therefore can be very helpful in establishing a definitive diagnosis. Similarly, antibodies to the Sm antigen have great specificity for SLE, but these antibodies are present in even fewer SLE patients (≈30%). The Sm antigen is a component of extractable nuclear antigens (ENAs), a term that refers to a heterogeneous mixture of non-DNA nuclear antigens that can be “extracted” from cells in the laboratory. These antigens are primarily ribonucleoproteins that can be divided into two major subsets based on their susceptibility to digestion by ribonuclease. The ribonuclease-sensitive antigens are designated RNP. Ribonuclease-resistant antigens are designated Sm (because these antibodies were first detected in a patient named Smith). Unlike anti-Sm, anti-RNP is not specific for SLE. However, high titers of anti-RNP antibodies can be helpful in supporting the diagnosis of MCTD.¹²¹

Numerous other autoantibodies can be found in patients with SLE. Antibodies to cytoplasmic antigens, such as Ro and La (SSA and SSB), can be found in some patients with SLE. Although these autoantibodies lack both sensitivity and specificity for SLE, they sometimes are associated with distinct clinical syndromes. The best example of such a relationship involves the presence of anti-Ro antibodies in more than 90% of cases of neonatal lupus.^{122,123} Anti-Ro antibodies are also seen with increased frequency in patients with SCLE.¹²⁴ Other autoantibodies may be directed against cell surface molecules or against circulating proteins. For example, antibodies to blood components can be responsible for hemolytic anemia, neutropenia, or thrombocytopenia, and antibodies to phospholipids can be detected in some SLE patients with or without antiphospholipid syndrome (see Chapter 82). It should be noted that rheumatoid

Table 80-7 Autoantibodies and Clinical Significance in Systemic Lupus Erythematosus (SLE)

Autoantibody	Prevalence in SLE	Clinical Significance
Antinuclear Antibody		
Anti-dsDNA	60%	95% specificity for SLE; fluctuates with disease activity; associated with glomerulonephritis
Anti-Smith	20%-30%	99% specificity for SLE; associated with anti-U1RNP antibodies
Anti-U1RNP	30%	Antibody associated with mixed connective tissue disease and lower frequency of glomerulonephritis
Anti-Ro/SSA	30%	Associated with Sjögren's syndrome, photosensitivity, SCLE, neonatal lupus, congenital heart block
Anti-La/SSB	20%	Associated with Sjögren's syndrome, SCLE, neonatal lupus, congenital heart block, anti-Ro/SSA
Antihistone	70%	Also associated with drug-induced lupus
Antiphospholipid	30%	Associated with arterial and venous thrombosis, pregnancy morbidity

SCLE, subacute cutaneous lupus erythematosus.

factor (anti-IgG) can be found in 15% to 20% of people with SLE, whether or not joint disease is present.¹²⁵ Anti-CCP antibodies can also be present.

Complement consumption arising from immune complex disease may lead to hypocomplementemia in patients with SLE.^{126,127} Because hypocomplementemia is rare in other diseases, its presence in a patient with SLE can provide valuable supportive evidence for the diagnosis. Moreover, because hypocomplementemia most likely reflects complement activation by immune complexes, its presence is often a sign of active disease. However, hereditary complement deficiencies may be found in patients with SLE (C1q, C2, C4), so absence of a particular complement component does not always reflect consumption.¹²⁸⁻¹³⁰ For this reason, it is often necessary to measure more than one complement component (e.g., C3 and C4) before concluding that hypocomplementemia is due to active disease.

The utility of serologic tests in assessing disease activity and predicting disease flares remains a topic of controversy. In the absence of a hereditary complement deficiency, hypocomplementemia is a reliable indicator that the disease is active, but normal complement levels do not rule out active disease. Titers of anti-dsDNA antibodies correlate with disease activity in some patients, but not in others. One recent study attempted to resolve the long-standing debate about the prognostic value of changes in lupus serology.¹³¹ In this study, patients with clinically quiescent lupus underwent monthly monitoring for levels of anti-dsDNA, C3a, C3, C4, and CH50 to identify patients with serologically active, clinically quiescent disease. These patients were then randomized to treatment with corticosteroids or placebo to determine whether treatment of serologically active disease could prevent impending clinical flares. The results were equivocal. Some patients with serologically active disease flared, and some flares were apparently prevented. However, in most control subjects, serologic deterioration was not followed by a clinical flare, and most of the flares that occurred in the original patient population that had been monitored were not preceded by serologic deterioration. Thus, there remains no substitute for knowledge of a particular patient's pattern or whether there is an association between clinical and serologic manifestations in that patient.

DIFFERENTIAL DIAGNOSIS

Because of the involvement of multiple organ systems and the lack of specificity of symptoms and/or signs, many systemic diseases can mimic SLE. Thus, before a diagnosis of SLE is established, a comprehensive search for infectious, malignant, and other autoimmune diseases must be undertaken.

Several viral infections can produce symptoms and signs that are present in SLE. In addition, many viral illnesses are associated with the production of autoantibodies. A careful patient history with serologic testing for the potential pathogen should help to secure the correct diagnosis. Parvovirus B19 classically presents with fever, rash, symmetric inflammatory polyarthritis, and cytopenias. Furthermore, the presence of ANA, anti-dsDNA, and hypocomplementemia has been observed in a few cases. Cytomegalovirus and Epstein-Barr virus can mimic SLE in that patients often

present with fatigue, cytopenias, abdominal pain, and liver test abnormalities. Acute HIV infection typically presents with fever, diffuse lymphadenopathy, and oral ulcers. Patients with hepatitis B and C can develop inflammatory arthritis and positive autoantibodies.

Malignancy, particularly non-Hodgkin's lymphoma, can manifest with constitutional symptoms, joint pain, cytopenias, lymphadenopathy, rash, and a positive ANA. One must be particularly alert to the possibility of malignancy in an older patient presenting with a new lupus-like syndrome. It is important to ensure that patients undergo appropriate malignancy screening tests.

Other autoimmune diseases such as RA, dermatomyositis, and Still's disease often share similar clinical features with SLE. Differentiating between these disorders might be difficult in early phases of the disease. Patients with RA and SLE may develop a symmetric inflammatory arthritis with a predilection for the wrists and small joints of the hands. ANA and rheumatoid factor (RF) may be elevated in both disorders, although anti-CCP antibody suggests RA, and anti-dsDNA or anti-Sm suggests SLE. The photosensitive, erythematous rashes of dermatomyositis and SLE can appear clinically and histopathologically identical. A careful patient history and supporting serologies will aid in making the correct diagnosis. Mixed connective tissue disease (MCTD) must also be considered when evaluating a patient for possible SLE. MCTD is a syndrome characterized by a high-titer anti-RNP antibody in conjunction with clinical features that are often present in SLE, scleroderma, and/or polymyositis. Patients frequently present with puffy, swollen hands and Raynaud's phenomenon. In contrast to SLE, patients with MCTD can develop an erosive arthritis that looks very similar to RA.

Careful evaluation for drug-induced lupus should be undertaken in every new patient in whom the diagnosis of SLE is suspected. This is especially important in an older person presenting with a lupus-like syndrome. Arthralgia, myalgia, fever, and serositis are common manifestations. A wide variety of drugs have been implicated in the development of drug-induced lupus; minocycline, procainamide, hydralazine, isoniazid, interferon alpha, and anti-TNF agents are well-known culprits. Hydrochlorothiazide is associated with SCLE. All of these drugs may cause a positive ANA. Minocycline is occasionally associated with anti-dsDNA antibodies and perinuclear-staining antineutrophil cytoplasmic antibodies (P-ANCA), and anti-TNF agents can cause positive anti-dsDNA antibodies. Antihistone antibodies are present in more than 95% of cases of drug-induced lupus, with the exception of those cases caused by minocycline. However, antihistone antibodies cannot be used to confirm a diagnosis of drug-induced lupus because up to 80% of idiopathic SLE patients will also produce antihistone antibodies.

NEONATAL LUPUS

Neonatal lupus is a passively acquired autoimmune disease of neonates that results from transplacental passage of maternal anti-SSA and/or anti-SSB antibodies.¹³² It can occur in mothers with SLE, in those with Sjögren's syndrome, or in patients in whom an autoimmune disease has not been diagnosed. Neonatal lupus can involve multiple

organ systems, including heart, skin, liver, and the hematologic system; the most severe complications are congenital complete heart block and cardiomyopathy.¹³³ The term *neonatal lupus* stems from early observations that the skin lesions in affected newborns were similar to the lesions of SCLE.

Congenital complete heart block is associated with a neonatal mortality rate as high as 20%, and most patients will eventually require a permanent pacemaker. This complication occurs in up to 2% of babies born to mothers who are positive for anti-Ro/SSA and/or anti-La/SSB antibodies. Once a woman has given birth to a baby with complete heart block, the risk for recurrence in a subsequent pregnancy is approximately 15%. Evidence from in vitro studies suggests that during fetal development, fetal cardiocytes undergo apoptosis that results in expression of Ro/SSA and La/SSB on the cell surface. Binding of anti-Ro/SSA and/or anti-La/SSB to fetal cardiocytes leads to inflammatory injury and subsequently to fibrosis of the atrioventricular (AV) node and surrounding tissue. The sinoatrial (SA) node may also be involved. Prospective studies have shown that the vulnerable period for the fetal heart is between 16 and 24 weeks of gestation. Thus, it is recommended that mothers with anti-Ro/SSA and/or anti-La/SSB antibodies undergo monitoring with fetal echocardiography beginning at 16 weeks' gestation. The hope has been that detection of early stages of heart block (first-degree and second-degree block) might allow for treatment that would prevent progression to third-degree heart block. Currently, the treatment of choice is maternal administration of a fluorinated glucocorticoid such as dexamethasone. Fluorinated glucocorticoids are preferred because of their ability to cross the placenta and enter the fetal circulation. However, treatment of incomplete fetal heart block remains controversial because the benefits have not been clearly delineated, and glucocorticoids have been associated with several fetal side effects such as intrauterine growth retardation, oligohydramnios, and adrenal suppression. Complete heart block is irreversible even with treatment, and first- or second-degree heart block may or may not reverse with treatment. Complicating matters, complete heart block can occur in the absence of preceding first- or second-degree block. In addition to conduction blocks, structural cardiac abnormalities have been observed in the setting of neonatal lupus, including, but not limited to, patent ductus arteriosus, ventricular septal defect, atrial septal defect, and patent foramen ovale. Myocarditis and pericarditis have also been described.

Rash, a common manifestation of neonatal lupus, consists of erythematous, annular lesions that resemble the annular subtype of SCLE. The rash typically occurs on the scalp, face, trunk, and extremities with a predilection for the periorbital area; it often develops after exposure of the newborn to ultraviolet light. Lesions typically occur within the first 4 to 6 weeks of life but may be present at birth. The rash is self-limiting and does not necessitate treatment. Lesions tend to resolve by 6 months of age, at which time maternal anti-Ro/SSA and/or anti-La/SSB antibodies are no longer present in the baby's circulation. Less common manifestations of neonatal lupus include hepatic, hematologic, and neurologic involvement.¹³⁴ Hepatic manifestations include asymptomatic elevation of liver function tests, hepatitis, hepatomegaly, cholestasis, and cirrhosis.

Hematologic manifestations include thrombocytopenia, autoimmune hemolytic anemia, and leukopenia. Neurologic complications, including myelopathy, seizures, and aseptic meningitis, have been reported.

Treatment of Systemic Lupus Erythematosus

GEORGE BERTSIAS •
ANTONIOS FANOURLAKIS •
DIMITRIOS T. BOUMPAS

KEY POINTS

The standard of care for SLE with severe, major organ involvement involves the combination of high-dose glucocorticoids with pulses of intravenous cyclophosphamide (CYC). However, this regimen is associated with significant toxicity including gonadal failure in young women. Mycophenolate mofetil (MMF) is at least equally effective and has a better toxicity profile than CYC in the treatment of moderately severe proliferative lupus nephritis (PLN). Maintenance of renal remission in moderate to severe PLN may be achieved with both azathioprine and MMF.

In lupus nephritis refractory to standard immunosuppressive therapy, calcineurin inhibitors (cyclosporin A, tacrolimus) have demonstrated some efficacy exerting significant antiproteinuric effects.

SLE pregnancies are considered high risk for maternal and fetal complications, underscoring the importance of family counseling and planning before pregnancy is sought. Common effective means of contraception are generally safe in SLE patients.

Pediatric-onset SLE is associated with high disease severity and rapid damage accrual. Treatment is guided by experience obtained in adult patients and involves the combination of glucocorticoids and immunosuppressive agents for severe manifestations.

Infections contribute to significant morbidity in SLE. Strategies to decrease their impact include (1) education aimed at both patients and physicians; (2) immunizations similar to those available to the general population; (3) minimization of exposure to glucocorticoids; and (4) prompt initiation of antimicrobial therapy in suspected infection.

The realization that a significant proportion of SLE patients features disease- and treatment-related comorbidities has shifted attention to adjunct therapies and primary prevention strategies such as renoprotective and cardiovascular disease risk reduction measures.

CLINICAL COURSE AND GENERAL TREATMENT STRATEGY

KEY POINTS

Treatment of moderate or severe systemic lupus erythematosus (SLE) requires an initial period of intensive immunosuppressive therapy (induction therapy) to control aberrant immunologic activity, recover function, and halt tissue injury, followed by a longer period of less intense and less toxic therapy (maintenance therapy) to consolidate remission and prevent future flares.

SLE patients experience poor quality of life, which is only in part associated with disease activity and organ damage.

The management of systemic lupus erythematosus (SLE) is challenging due to the clinical heterogeneity and the unpredictable course of the disease.¹ SLE activity usually follows the flare pattern, which is characterized by a relapsing-remitting course. However, an equal number of patients have continuously active disease, and only a few have long periods of disease quiescence.^{2,3} Despite improvements in overall survival (85% to 90% during the first 10 years), some SLE patients are still at risk for premature death.^{4,5} Persistent inflammation inevitably results in irreversible major organ damage, which is linked to decreased quality of life and increased mortality.⁶ Accordingly, therapeutic strategies should aim at reducing overall burden of systemic inflammation. Achieving these goals requires (1) accurate assessment of disease activity and flares, (2) stratification according to severity of target organ involvement, (3) use of safe and effective drugs to induce remission promptly and prevent flares, and (4) prevention and management of disease and treatment-related comorbidities.⁷

In general, patients with mild lupus manifestations (skin, joint, and mucosal involvement) are treated with antimalarials or disease-modifying antirheumatic drugs (DMARDs), alone or in combination with low-dose oral glucocorticoids (GCs). Severe SLE with major organ involvement requires an initial period of intensive immunosuppressive therapy (*induction therapy*) to control aberrant immunologic activity and halt tissue injury, followed by a longer period of less intensive and less toxic *maintenance therapy*, to consolidate remission and prevent flares.⁸ Immunosuppressive therapy enables for the use of lower GC doses, thus reducing its deleterious effects.

SLE patients experience poor quality of life, which is only in part associated with disease activity and organ damage. Important contributors include fatigue, fibromyalgia, depression, and cognitive dysfunction.^{9,10} Treating physicians should regularly address these issues and engage symptomatic or remedial therapies as indicated. The realization that a significant proportion of patients features disease- and treatment-related comorbidities has shifted attention to adjunct therapies and primary prevention strategies such as renoprotective and cardiovascular disease risk reduction measures.

PATIENT AND PHYSICIAN PREFERENCES

KEY POINTS

Patients have a preference for full disclosure of medication risks and treatment alternatives. They also favor an active or collaborative role in decision making involving their health care.

Health professionals are increasingly encouraged to involve patients in treatment decisions, recognizing them as experts with a unique knowledge of their own health and their preferences for treatments, health states, and outcomes.¹¹ This approach may be particularly challenging in patients with severe lupus who may benefit from cytotoxic therapy, which is, however, associated with significant toxicity. This was demonstrated in a study of 93 well-educated women with mild lupus and good health status who were presented with descriptions of cyclophosphamide (CYC) and azathioprine (AZA) and were then asked to indicate their preferred choice of hypothetical treatment.¹² The study patients had a strong preference for full disclosure of medication risks and treatment alternatives, and they preferred a collaborative role in decision making involving their health care. Nearly all (98%) participants chose AZA over CYC when both drugs conferred an equal probability of renal survival. Although most subjects switched preferences to CYC for better renal survival, a significant proportion (15% to 31%) were unwilling to switch to CYC for improved short- or long-term renal survival. Preference for the long-term benefits of CYC was greater among college than high school graduates, which could reflect a better understanding of the probabilities presented in the study among those with a higher education level. This underscores the importance of providing patients with tailored information to ensure that all patients accurately perceive the risks and benefits related to prescribed medications.

On the other hand, the relative paucity of high-quality evidence to guide therapeutic decisions for various disease manifestations has been a cause for practice pattern variation among lupus experts. Many opinions about the treatment of lupus are based on personal perception rather than valid observation. To facilitate physicians who are in the care of these patients, the European League Against Rheumatism (EULAR) Task Force on SLE has developed management recommendations based on evidence and expert opinion (see Evidence and Expert-based Recommendations in SLE later).

DRUGS USED IN THE TREATMENT OF SYSTEMIC LUPUS ERYTHEMATOSUS

KEY POINTS

The target dose of glucocorticoids should be 0.25 mg/kg every other day for 2 to 3 months, which is acceptable for long-term use. Concomitant use of immunosuppressive agents facilitates tapering and decreases cumulative toxicity.

Antimalarials are effective for skin and mucocutaneous manifestations. Their use has been associated with reduced organ damage accrual.

Azathioprine (AZA) is effective as an induction and a maintenance regimen in mild to moderate SLE including nephritis.

The combination of high-dose glucocorticoids with pulses of intravenous CYC remains the standard of care for severe SLE with major organ involvement.

MMF is at least equally efficacious and has a better toxicity profile than CYC in the treatment of moderately severe PLN.

Calcineurin inhibitors (cyclosporin A, tacrolimus), used alone or in combination with other immunosuppressive agents, have demonstrated efficacy in refractory to cytotoxic therapy lupus nephritis.

Based on evidence from uncontrolled studies, the American College of Rheumatology and the European League Against Rheumatism–European Renal Association have included rituximab (anti-CD20 mAb) as a therapeutic option for selected cases of lupus nephritis refractory to conventional immunosuppressive treatment.

There is an unprecedented array of promising biologic therapies currently in development in SLE.

Glucocorticoids

GCs exert broad inhibitory effects on immune responses mediated by T and B cells, as well as on the effector functions of monocytes and neutrophils. On the basis of these effects and their rapid onset of action, GCs have been remarkably efficacious in managing acute SLE manifestations. However, only two small randomized controlled trials (RCTs) have been conducted to demonstrate their efficacy in lupus.^{13,14}

Low-dose GC therapy (≤ 7.5 mg prednisone equivalent per day) is generally used when other initial therapies (antimalarials) are not tolerated or are inadequate to control disease activity. In moderate to severe disease, GCs are used as either single or background therapy in combination with immunosuppressive agents, at doses 0.5 to 1 mg/kg prednisone equivalent in a single dose usually in the morning. When combined with immunosuppressive agents, the GC dose should rarely exceed 0.5 to 0.6 mg/kg prednisone due to concerns for infections and other toxicities. Tapering of GC dose starts after the first 4 to 6 weeks of therapy, targeting a dose of 0.25 mg/kg every other day at 2 to 3 months, which is acceptable for long-term use. Concomitant use of immunosuppressive agents facilitates tapering and decreases cumulative GC toxicity.

Tseng and colleagues¹⁵ examined the effect of a short course of moderate-dose GC in preventing flares in clinically stable but serologically active SLE. Severe flares, requiring increase in prednisone dose or addition of an immunosuppressive agent, or both, occurred in 6 out of 20 patients on placebo, as compared with none of the 21 patients who took prednisone (30 mg for 2 weeks, 20 mg for 1 week, and 10 mg for 1 week). The results agree with those of Bootsma and colleagues¹³ and suggest that in clinically stable but serologically active SLE patients, short-term GC therapy may avert a severe flare. This effect must be balanced against risks for overtreating patients with higher cumulative GC doses.

In severe, rapidly progressing disease or when doses greater than 0.6 mg/kg/day prednisone equivalent are required to control disease activity, GC pulse therapy may be introduced.^{16,17} Intravenous (IV) pulses of methylprednisolone (MP) (250 to 1000 mg daily for 1 to 3 consecutive days) are used, although there is no strong evidence to support a survival advantage. In addition to expediting

remission, IV-MP pulses may allow for the use of lower GC doses during the induction period. In a trial from the National Institutes of Health (NIH), 82 patients with moderate to severe proliferative lupus nephritis (PLN) were randomized to receive sequential induction-maintenance therapy with IV-MP alone, IV-MP plus IV-CYC, or IV-CYC alone.¹⁸ Renal remission was significantly more common in both IV-CYC groups regardless of whether or not they received IV-MP. In the extended follow-up of the trial cohort, an analysis of protocol completers found that doubling of serum creatinine (SCr) was significantly lower in the combination group than in the IV-CYC group (relative risk [RR] 0.095).¹⁹ These findings indicate that combining IV-CYC with IV-MP in the treatment of lupus nephritis (LN) may confer an advantage in long-term renal outcomes without added toxicity.

GC toxicity may involve early (mood effects, acne, myalgias, infections); later (metabolic); and late-onset (osteoporosis, avascular bone necrosis, cataract, cardiovascular disease) adverse events. Although confounded by increased systemic disease activity, most effects are considered to be dependent on the cumulative dose and duration and, to a lesser extent, route of administration. Tailoring GC use on the basis of individual patient profile (disease activity, risk for toxicity) and prompt initiation of primary prevention measures (antiosteoporotic treatment) is of paramount importance.

Antimalarials and DMARD Therapy

Hydroxychloroquine

Antimalarial drugs, mainly chloroquine and hydroxychloroquine (HCQ), are commonly prescribed to SLE patients with skin and joint manifestations but are increasingly identified as an adjuvant treatment for achieving remission in severe lupus. A systematic review concluded that use of antimalarials resulted in a greater than 50% reduction in general SLE disease activity and to a moderate reduction in severe flares and GC dose.²⁰ Beneficial effects on the lipid profile and subclinical atherosclerosis markers have also been described. Intriguingly, prospective observational studies have reported an inverse association between use of HCQ and accrual of irreversible organ damage, as measured using the Systemic Lupus International Collaborating Clinics–American College of Rheumatology Damage Index (SDI) (adjusted hazard ratio [HR], 0.73), and overall mortality rates (adjusted HR, 0.14 to 0.32).²⁰ Although these findings may be confounded by milder forms of disease usually present in SLE patients who are prescribed antimalarials, the presumptive mode of action of antimalarials by inhibition of innate immunity pathways provides a plausible explanation for their multifold beneficial effects.²¹ HCQ is well tolerated with low rates of mild gastrointestinal and skin adverse events. Retinal toxicity is uncommon (estimated at 0.1% in patients who received HCQ for more than 10 years²⁰), but routine ophthalmologic evaluation is recommended (annual screening during the first 5 years of usage is recommended for individuals who are treated with high HCQ dose [>6.5 mg/kg], for those treated more than 5 years, or for those who have other complicating factors).²²

Methotrexate

Methotrexate (MTX), an antifolate agent commonly prescribed for rheumatoid arthritis (RA), has been used as steroid-sparing treatment for articular and cutaneous manifestations of SLE.²³ MTX is administered weekly either orally or parenterally. Concomitant administration of folic acid (2.5 to 5 mg/week, not until 24 hours after the intake of MTX) is recommended to minimize toxicity (Table 81-1). Fortin and colleagues²⁴ evaluated the efficacy of MTX in a 12-month placebo-controlled RCT in 86 SLE patients. Patients had mild to moderate disease, with musculoskeletal (93%), cardiovascular (74%), and hematologic (69%) manifestations. Approximately half of the patients in each group were on oral prednisone, whereas 41 patients in the placebo group versus 27 in the MTX group were on antimalarials. Among participants with comparable baseline prednisone dose, those on MTX received on average 1.33 mg/day less prednisone during the trial period compared with those in the placebo group. Fewer patients in the MTX group were also started on GCs (5% vs. 26% in the placebo group). MTX use was associated with a reduction in the mean during-trial Systemic Lupus Activity Measure (SLAM) score of 0.86 units. Together, these data suggest that MTX could be a reasonable alternative steroid-sparing agent in mild to moderate SLE.

Leflunomide

Leflunomide, currently used in RA, has been used in LN refractory or intolerant to standard immunosuppressive therapy. Leflunomide requires a loading dose of 100 mg/day for 3 days followed by 20 mg/day thereafter. In a multicenter observational study, 110 patients with biopsy-proven PLN were assigned to either oral leflunomide or IV-CYC (monthly pulses 0.5 g/m²), both in combination with oral prednisone (0.8 mg/kg/day for 4 weeks, then tapered).²⁵ After 6 months, complete and partial remission rates were 21% and 52% in the leflunomide group and 18% and 55% in the IV-CYC group, respectively. Repeat kidney biopsies showed significant reduction in activity index and pathologic transformation of 10 cases of diffuse to focal PLN. Similar rates of adverse events were observed in the two study groups and included mostly herpes zoster infection, alopecia, and hypertension. Better-designed RCTs are necessary to establish the efficacy, if any, of leflunomide in PLN. The drug is teratogenic and is contraindicated in patients who are trying to become or are pregnant.

Cytotoxic Therapy

Cyclophosphamide

Pharmacology and Route of Administration. CYC is an alkylating agent that depletes both T and B cells and reduces the production of autoantibodies in lupus. Both oral and IV administration of CYC result in similar plasma concentrations, and the serum half-life is approximately 6 hours. CYC is metabolized to various active metabolites by cytochrome P-450 in the liver or other tissues such as transitional epithelial cells of the bladder or lymphocytes. Drugs that induce hepatic microsomal enzymes (barbiturates,

Table 81-1 Recommended Therapeutic Drug Monitoring in Systemic Lupus Erythematosus

Drug	Dosage	Dose Adjustment	Toxicities Requiring Monitoring	Baseline Evaluation	Laboratory Monitoring
Azathioprine	50-100 mg/day in 1-3 doses with food	↓ 25% if eGFR 10-30 mL/min; ↓ 50% if eGFR < 10 mL/min	Myelosuppression, hepatotoxicity, lymphoproliferative diseases	CBC, platelets, SCr, AST or ALT	CBC and platelets every 2 wk with changes in dosage; baseline tests every 1-3 mo
Mycophenolate mofetil	1-3 g/day in 2 divided doses with food	Maximum 1 g/day if eGFR < 25 mL/min	Myelosuppression, hematotoxicity, infection	CBC, platelet, SCr, AST or ALT	CBCs and platelets every 1-2 wk with changes in dosage; baseline tests every 1-3 mo
Cyclophosphamide	50-150 mg/day in a single dose with breakfast. Lots of fluids (at least 3 L water/day), empty bladder before bedtime	↓ 25% if eGFR 25-50 mL/min; ↓ 30-50% if eGFR < 25 mL/min; ↓ 25% if serum Bil 3.1-5 mg/dL or transaminases >3 times ULN	Myelosuppression, hemorrhagic cystitis, myeloproliferative disease, malignancies	CBC, platelet, SCr, AST or ALT, urinalysis	CBC with differential every 1-2 wk, with changes in dosage and then every 1-3 mo; keep WBC > 4000/mm ³ with dose adjustment; urinalysis, AST or ALT every 3 mo; urinalysis every 6-12 mo following cessation
Methotrexate	7.5-15 mg/wk in 1-3 doses with food or milk/water	↓ 50% if eGFR 10-50 mL/min; avoid use if eGFR < 10 mL/min; avoid use in hepatic dysfunction (serum Bil 3.1-5 mg/dL or transaminases >3 times ULN)	Myelosuppression, hepatic fibrosis, pneumonitis	CxR, hepatitis B/C serology in high-risk patients, AST or ALT, SAlb, ALP, SCr	CBC with platelet, AST, SAlb, SCr every 1-3 mo
Cyclosporin A	100-400 mg/day in 2 doses at the same time every day with meal or between meals	Avoid in impaired renal function	Renal insufficiency, anemia, hypertension	CBC, SCr, uric acid, AST or ALT, SAlb, ALP, blood pressure	SCr every 2 wk until dose is stable, then monthly; CBC, potassium, AST or ALT, SAlb, and ALP every 1-3 mo; drug levels only with doses > 3 mg/kg/day
Tacrolimus	1-3 mg/day in 2 doses at the same time every day	Cautious use in liver or renal insufficiency	Renal insufficiency, neurotoxicity, malignancy, infections, hyperkalemia	SCr, potassium, AST or ALT, glucose, blood pressure	Baseline tests once a week for the first 3-4 wk, then every 1-3 mo; monitor drug trough levels
Leflunomide	100 mg/day in a single dose for 3 days, then 10-20 mg/day	Avoid in hepatic dysfunction (serum Bil 3.1-5 mg/dL or transaminases >3 times ULN)	Myelosuppression, hepatotoxicity, fetal toxicity	CBC, SCr, AST or ALT, SAlb, ALP	CBC, AST or ALT, SAlb, and ALP monthly for 6 mo, then every 1-3 mo; monthly monitoring if MTX coadministered
Rituximab	1000 mg on day 1 and 15	None	HBV reactivation (rare)	CBC, SCr, AST or ALT, HBV serology (high-risk patients), TST	CBC and platelets

ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; Bil, bilirubin; CBC, complete blood cell count; CxR, chest x-ray; eGFR, estimated glomerular filtration rate; HBV, hepatitis B; LFTs, liver function tests; MTX, methotrexate; SAlb, serum albumin; SCr, serum creatinine; TST, tuberculin skin testing; ULN, upper limit of normal; WBC, white blood cell count.

alcohol, phenytoin, rifampin) may accelerate the metabolism of CYC into its active metabolites and thus increase its pharmacologic and toxic effects. Conversely, drugs that inhibit the hepatic microsomal enzymes (antimalarials, tricyclic antidepressants, and allopurinol) may slow the conversion of CYC to active metabolites. Approximately 20% of the drug is excreted by the kidney, whereas 80% is

processed by the liver. Dose modification is necessary for patients with renal impairment but not in liver disease.

The NIH trials demonstrated equivalent efficacy yet lower toxicity with monthly IV (0.5 to 1 g/m²) versus oral regimens, which led to the predominant use of IV-CYC in clinical practice (Table 81-4). Reversible myelotoxicity is common and dose related. After pulse therapy, the nadir of

lymphocyte count occurs on days 7 to 10 and that of granulocyte count on days 10 to 14. The risk of infection increases with a white blood cell count less than 3000 cells/mm³, so the dose should be adjusted to keep it above this level (see Table 81-1). A prompt recovery from granulocytopenia usually occurs after 21 to 28 days. Thrombocytopenia is rare in CYC monotherapy. Reversible alopecia and nausea are common, whereas infections (especially herpes zoster), gonadal toxicity, and malignancy (including bladder toxicity and carcinoma) are less frequent though much more serious adverse events (see Comorbidities in Systemic Lupus Erythematosus and Women's Health Issues later).

Use in Lupus Nephritis. RCTs with long-term follow-up have shown that intermittent pulse IV-CYC therapy is effective for moderate to severe PLN.³³ CYC may retard progressive renal scarring, preserve renal function, and reduce the risk for the development of end-stage renal disease (ESRD) requiring dialysis or renal transplantation. Following induction therapy, a maintenance regimen is necessary to decrease the risk of flares.³⁴ NIH studies have demonstrated that combination pulse therapy with IV-CYC and IV-MP improves renal outcomes without increasing toxicity.^{18,19} On the basis of these studies, the authors propose 7 monthly pulses of IV-CYC (0.5 to 1 g/m²) followed by quarterly pulses for at least 1 year beyond remission. For patients with moderate to severe disease, monthly pulses of IV-MP are given during the induction period.

Because of toxicity concerns and the appreciation that the disease may be less severe in whites, European investigators sought alternative IV-CYC protocols. In the Euro-Lupus Nephritis Trial involving mostly patients with milder forms of disease (mean SCr, 1.2 mg/dL; mean proteinuria, 3 g/day), less intensive regimens of IV-CYC (6 fortnightly pulses at a fixed dose of 500 mg each in combination with three daily doses of 750 mg of IV-MP) followed with AZA as maintenance had comparable efficacy and less toxicity than high-dose IV-CYC (8 pulses).³⁵ Mean survival rate at 10 years was 92% for both groups; ESRD and doubling of SCr rates did not differ between the two groups.³⁶ Therefore low-dose IV-CYC may be an alternative option for white patients with moderately severe LN.

Austin and colleagues³⁷ compared cyclosporin A (5 mg/kg/day, then adjusted according to changes in SCr), IV-CYC (0.5 to 1 g/m² × 6 monthly doses), and GC alone in an RCT in 42 patients with lupus membranous nephropathy (LMN) (median GFR, 83 mL/min/1.73 m²; median proteinuria, 5.4 g/day). All patients received alternate-day oral prednisone (1 mg/kg every other day for 8 weeks, then tapered to 0.25 mg/kg every other day). At 1 year, the cumulative probability of remission was 27% with prednisone, 60% with IV-CYC, and 83% with CsA. Rates of nephrotic syndrome relapse per 100 patient-months were 2.0 with CsA versus 0.2 with IV-CYC. Thus although IV-CYC and CsA are equally effective as induction therapy in LMN, CsA may require maintenance therapy (with lower doses of CsA, or AZA, or MMF) to prevent relapses.

Use in Extrarenal Disease. CYC has demonstrated efficacy in life-threatening extrarenal lupus manifestations such as severe thrombocytopenia (platelet count <20,000/mm³), neurologic disease, abdominal vasculitis, acute pneumonitis/alveolar hemorrhage, and extensive skin disease.^{38,39} Barile-Fabris and colleagues⁴⁰ have reported

superiority of IV-CYC against IV-MP for severe nonthrombotic neurologic SLE. In this trial, 32 patients were randomized to receive 3 pulses of 1 g of IV-MP followed by one of the following two treatments: pulses of 1 g IV-MP (monthly for 4 months, then every 2 to 3 months for 1 year) or IV-CYC (0.75 g/m² monthly for 1 year and then every 3 months for another year). Seizures were the most common syndrome; other manifestations included peripheral neuropathy, optic neuritis, transverse myelitis, brain stem disease, coma, and internuclear ophthalmoplegia. Clinical response was observed in 18 of 19 patients who received IV-CYC as compared with 7 of 13 who received IV-MP. Thus the combination of pulses of IV-MP with IV-CYC is considered as treatment of choice for severe inflammatory neurologic SLE.

Other Agents

Chlorambucil. Chlorambucil (CAB) is an aromatic alkylating agent with substitution of the *N*-methyl group of mechlorethamine with phenylbutyric acid. The drug is given orally (0.1 to 0.2 mg/kg/day) with good absorption. The effects on immune functions are comparable with those described for CYC. Adverse events are also similar to those of CYC, except for bladder toxicity. More prolonged and less predictable bone marrow suppression can be observed. CAB has been associated with increased risk for leukemia. There is limited experience with the use of CAB in SLE, yet favorable outcomes in renal and extrarenal manifestations such as neuropsychiatric, vasculitis, and multiorgan involvement have been reported. In a retrospective study of 19 patients with predominantly LMN, Moroni and colleagues⁵⁶ showed that CAB combined with alternate-month cycles of IV-MP was more effective than IV-MP alone in inducing remission of nephrotic syndrome (64% vs. 38%) and preserving renal function over a period of 83 months. However, the use of CAB for LMN or other lupus manifestations is limited.

Fludarabine. Fludarabine induces profound immunosuppression by depleting T and B lymphocytes and is used in the treatment of hematologic malignancies. A single pilot study in patients with active PLN was terminated prematurely due to severe hematologic toxicity.⁵⁷ It is unlikely that fludarabine will be used in SLE.

Antimetabolites Calcineurin Inhibitors

Azathioprine

AZA interferes with the de novo synthesis of inosinic acid and inhibits the conversion of purine bases such as inosine to adenine and guanine ribonucleotides. AZA in doses of 2 to 2.5 mg/kg/day has been remarkably safe in the long term without significantly increasing the risk for infection, whereas it is associated with a marginally increased risk for malignancy. Gastrointestinal complaints are frequent, leading 15% to 30% of patients to discontinue the drug within 6 months. Mild liver enzyme elevation may occur, but severe liver injury is rare. Reversible, dose-related bone marrow toxicity is also common; leukopenia is encountered in approximately 4.5% and thrombocytopenia in 2% of patients receiving low-dose AZA (see Table 81-1). Notably,

AZA toxicity is idiosyncratic and has been associated with genetic polymorphisms resulting in decreased thiopurine methyltransferase (TPMT) activity and impaired ability to detoxify intermediate metabolites.²⁶ Concomitant use of allopurinol substantially increases AZA toxicity and should be avoided.

In lupus, manifestations such as mild PLN, thrombocytopenia with platelet count in the range of 20 to 50 × 10³/mm³, and serositis may respond to AZA, usually in combination with moderate to high GC doses (Tables 81-2 and 81-3). Its efficacy as an induction-maintenance regimen has been tested in low-risk European patients with PLN who were randomized to receive pulse IV-CYC plus prednisone versus IV-MP plus AZA plus a tapering dose of prednisone.²⁷ After 2 years, both groups received maintenance therapy with AZA plus prednisone. The two groups did not differ in terms of induction of remission, mean SCr and proteinuria levels during the first 2 years. However, after a median follow-up duration of 5.7 years, rates of doubling of baseline SCr and of renal relapses were higher in the AZA group. Thus the authors believe that AZA may be used in mild LN and in patients strongly opposed to CYC.

AZA has also been considered a safe and efficacious option for maintenance of remission in SLE including cases of moderately severe PLN.^{28,29} Two RCTs have compared AZA versus mycophenolate mofetil (MMF) as maintenance regimens in PLN. In the MAINTAIN trial, which included only European patients, both agents were equally efficacious in terms of time-to-renal flare, number of severe flares, renal remission, and doubling of SCr.³⁰ In contrast, the ALMS trial, which included a larger number of patients with multiethnic backgrounds, reported increased renal flares in the AZA versus the MMF group (see Mycophenolate Mofetil later).³¹ To this end, both agents can be used as maintenance therapy on the basis of availability, clinical experience, and potential for pregnancy because MMF is associated with an increased risk of spontaneous abortion and fetal malformation. On the basis of their significant difference in cost, patients with mild to moderate LN, especially white individuals, could first be treated with AZA.³²

Mycophenolate Mofetil

Pharmacology. MMF is a prodrug of mycophenolic acid, a potent inhibitor of inosine monophosphate dehydrogenase

Table 81-2 Indications for Immunosuppressive Therapy in Systemic Lupus Erythematosus

General Indications	
Involvement of major organs or extensive involvement of nonmajor organs (skin) refractory to other agents, or both	
Failure to respond to or inability to taper corticosteroids to acceptable doses for long-term use	
Specific Organ Involvement	
Renal	
Proliferative or membranous nephritis (nephritic or nephritic syndrome), or both	
Hematologic	
Severe thrombocytopenia (platelets <20,000/mm ³)	
Thrombotic thrombocytopenic purpura–like syndrome	
Severe hemolytic or aplastic anemia, or immune neutropenia not responding to glucocorticoids	
Pulmonary	
Lupus pneumonitis or alveolar hemorrhage, or both	
Cardiac	
Myocarditis with depressed left ventricular function, pericarditis with impending tamponade	
Gastrointestinal	
Abdominal vasculitis	
Nervous System	
Transverse myelitis, cerebritis, optic neuritis, psychosis refractory to corticosteroids, mononeuritis multiplex, severe peripheral neuropathy	

that is indispensable for the de novo synthesis of guanosine nucleotides. The lack of any salvage nucleotide synthesis pathway in lymphocytes renders them a selective target for MMF. Conversely, other tissues with high proliferative activity (skin, intestine, neutrophils) that have an intrinsic salvage guanosine synthesis pathway can escape the anti-proliferative effects, which explains its more favorable toxicity profile compared with CYC. MMF has excellent oral bioavailability with peak levels occurring within 1 to 2 hours after administration and half-life of 17 hours. Although therapeutic drug monitoring to guide MMF dosing has been proposed in renal transplantation, validation of therapeutic MPA monitoring in LN is still required.⁴¹ Antacids and cholestyramine decrease the bioavailability

Table 81-3 Recommended Immunosuppressive Therapy for Major Organ Involvement in Systemic Lupus Erythematosus

Disease Severity	Induction Therapy	Maintenance Therapy
Mild	High-dose GC (0.5-1 mg/kg/day prednisone ×4-6 wk, tapered to 0.125 mg/kg every other day within 3 mo) alone or in combination with AZA (1-2 mg/kg/day) If no remission within 3 mo, treat as moderately severe	Low-dose GC (prednisone ≤0.125 mg/kg on alternative days) alone or with AZA (1-2 mg/kg/day)
Moderate	MMF (2 g/day) (or AZA) with GC as above; if no remission after the first 6-12 mo, treat as severe	Consider further gradual tapering at the end of each year of remission MMF tapered to 1.5 g/day for 6-12 mo and then to 1 g/day; consider further tapering at the end of each year in remission Alternative: AZA (1-2 mg/kg/day)
Severe	Pulse IV-CYC alone or in combination with pulse IV-MP for the first 6 mo (background GC 0.5 mg/kg/day for 4 wk, then taper) If no response, consider adding RTX or switch to MMF	Quarterly pulses of IV-CYC for at least 1 year beyond remission Alternative: AZA (1-2 mg/kg/day), MMF (1-2 g/day)

AZA, azathioprine; CYC, cyclophosphamide; GC, glucocorticoid; IV, intravenous; MMF, mycophenolate mofetil; MP, methylprednisolone; RTX, rituximab.

Table 81-4 National Institutes of Health Protocol for Administration and Monitoring of Pulse Intravenous Cyclophosphamide Therapy

Estimate GFR by standard methods (Cockcroft-Gault or the Modification of Diet in Renal Disease formula)
Calculate body surface area (m ²): BSA = $\sqrt{\text{Height (cm)} \times \text{Weight (kg)}/3600}$
Cyclophosphamide (Cytosan) (CYC) dosing and administration:
Initial dose 0.75 g/m ² (0.5 g/m ² if GFR less than one-third of expected normal)
Administer CYC in 150 mL normal saline IV over 30-60 min (alternative: equivalent dose of pulse CYC may be taken orally in highly motivated and compliant patients)
Determine WBC at days 10 and 14 after each CYC pulse (patient should delay prednisone until after blood tests drawn to avoid transient steroid-induced leukocytosis)
Adjust subsequent doses of CYC to maximum dose of 1 g/m ² to keep nadir WBC >1500/mm ³ . If WBC nadir falls <1500/mm ³ , decrease next dose by 25%
Repeat IV-CYC pulses monthly (every 3 wk in extremely aggressive disease) for another 6 mo (total 7 pulses), then quarterly for 1 year after remission is achieved (inactive urine sediment, proteinuria <1 g/day, normalization of complement (and ideally anti-dsDNA), and minimal or no extrarenal lupus activity)
Protection of urine bladder against CYC-induced hemorrhagic cystitis
Diuresis with 5% dextrose and 0.45% saline (2 L at 250 mL/hr). Frequent voiding; continue high-dose oral fluids for 24 hr. Patients return to clinic if they cannot sustain an adequate fluid intake
Consider mesna (each dose 20% of total CYC dose) intravenously or orally at 0, 2, 4, and 6 hr after CYC dosing. Mesna is especially important to use when sustained diuresis may be difficult to achieve or if pulse CYC is administered in an outpatient setting
If anticipating difficulty with sustaining diuresis (e.g., severe nephrotic syndrome) or with voiding (e.g., neurogenic bladder), insert a 3-way urinary catheter with continuous bladder flushing with standard antibiotic irrigating solution (e.g., 3 L) or normal saline for 24 hr to minimize risk of hemorrhagic cystitis
Antiemetics (usually administered orally)
Dexamethasone (10 mg single dose) <i>plus</i>
Serotonin receptor antagonists: granisetron 1 mg with CYC dose (usually repeat dose in 12 hr); ondansetron 8 mg three times daily for 1-2 days
Monitor fluid balance during hydration. Use diuresis if patient develops progressive fluid accumulation
Complications of pulse CYC
Expected: nausea and vomiting (central effect of CYC) mostly controlled by serotonin receptor antagonists; transient hair thinning (rarely severe at CYC doses ≤ 1 g/m ²)
Common: significant infection diathesis only if leukopenia not carefully controlled; modest increase in herpes zoster (very low risk of dissemination); infertility (male and female); amenorrhea proportional to age of the patient during treatment and to the cumulative dose of CYC. In females at high risk for persistent amenorrhea, consider using leuprolide 3.75 mg subcutaneously 2 wk before each dose of CYC

CYC, cyclophosphamide; GFR, glomerular filtration rate; IV, intravenous; WBC, white blood cell count.

of MMF, and the coadministration with AZA should be avoided. MMF may be teratogenic and should not be administered during pregnancy.

Use in Lupus Nephritis

Induction Therapy. Initial RCTs indicated equal or even superior efficacy of MMF over CYC in inducing remission in PLN, but their findings were limited by flaws in the design such as the low number of patients, the underrepresentation of severe forms of LN, and the short follow-up.^{28,42-44} The Aspreva Lupus Management Study (ALMS), one of the largest and most racially diverse RCT in LN that included a total of 370 patients, 27% of whom had estimated GFR less than 60 mL/min/1.73 m², failed to demonstrate superiority of MMF (2 to 3 g/day) over monthly pulses of IV-CYC (0.5 to 1 g/m²).⁴⁵ Both groups received oral prednisone, with a defined taper from a maximum starting dose of 60 mg/day. At 6 months, response rates were similar for both groups (56% for MMF, 53% for IV-CYC) and there were no differences in adverse events. Subsequently, three meta-analyses of RCTs have concluded that MMF is as effective as CYC (pooled relative risk [RR] for complete remission ranging 1.49 to 1.61) and has a better safety profile (pooled RR, 0.15 to 0.17 for amenorrhea; 0.41 to 0.78 for leukopenia; 0.77 to 0.83 for infections) as induction therapy for PLN.⁴⁶⁻⁴⁸ MMF may therefore be considered as induction therapy in moderately severe PLN, especially when gonadal toxicity is an issue.

MMF has demonstrated antiproteinuric effects in LMN,⁴⁹ but there is lack of large RCTs to formally test its efficacy.

A pooled analysis of 84 patients with pure LMN who participated in the ALMS trial⁴⁵ and in the study by Ginzler and colleagues⁴⁴ demonstrated comparable remission rates (percentage change of proteinuria and SCr were the primary end points) in MMF- and IV-CYC-treated patients.⁵⁰ A trial testing MMF monotherapy in idiopathic membranous nephropathy failed to demonstrate efficacy.⁵¹ More data are necessary to delineate the role of MMF in the management of LMN.

Maintenance Therapy. Contreras and colleagues²⁸ compared MMF versus AZA or quarterly pulses of IV-CYC as maintenance therapy in PLN following remission with 7 IV-CYC pulses. In this trial of 59 patients, 95% were black or Hispanic, 78% had diffuse PLN, with average SCr 1.6 mg/dL and serum albumin 2.7 mg/dL. After a follow-up of 72 months, MMF and AZA were superior to IV-CYC in terms of relapse-free survival (78% for MMF, 58% for AZA, 4% for IV-CYC), mortality, infections, and amenorrhea. This study was criticized for the insufficient number of patients to demonstrate superiority, the use of lower doses of IV-CYC, and the use of higher doses of GC, which may have decreased efficacy and increased the risk for infections. Two large multicenter RCTs have compared MMF versus AZA as maintenance regimen in PLN. The MAINTAIN Nephritis Trial included 105 European patients with moderately severe class III to IV PLN (10% had baseline SCr >1.4 mg/dL, 39% had proteinuria ≥ 3 g/day) who received induction therapy with 3 daily 750-mg IV-MP pulses followed by oral GC and 6 fortnightly IV-CYC pulses (500 mg per pulse).³⁰

On the basis of randomization performed at baseline, AZA (target dose: 2 mg/kg/day) or MMF (target dose: 2 g/day) was given at week 12 to all patients. Over a 3-year period, the two groups did not differ in terms of time-to-renal flare, number of severe flares, renal remission, or doubling of SCr. Adverse events did not differ between the groups except for blood cytopenias, which were more frequent in the AZA group. These results are different from those reported for the ALMS maintenance part.³¹ This study included 227 patients (44% nonwhites) and showed a failure rate of 32% in the AZA group versus 16% in the MMF group at 3 years after successful induction therapy during the first part of the study with either MMF or IV-CYC. Differences in the study design and the induction protocol, the number and ethnicity of the included patients, and the outcome measures may account for the discrepant results. Of note, an RCT in ANCA-positive vasculitis found that MMF was less effective than AZA for maintaining disease remission following induction therapy with IV-CYC and GC.⁵² To this end, both MMF and AZA may be used for maintenance of remission in PLN on the basis of availability and potential for pregnancy.

Use in Extrarenal Lupus. A systematic review of open-label trials concluded that MMF may be effective for refractory skin and blood manifestations in SLE.⁵³ A posthoc analysis of the ALMS trial data in LN patients showed that MMF was equally efficacious with IV-CYC pulse therapy (both in combination with tapered prednisone) on general disease activity.⁵⁴ At week 24, BILAG-defined remission was achieved in the general (100% in MMF vs. 94% in IV-CYC), mucocutaneous (84% vs. 93%), musculoskeletal (91% vs. 96%), and hematologic (60% vs. 67%) domains. Normalization of C3/C4 and anti-dsDNA titers also occurred at a similar rate. Conversely, MMF showed no efficacy in preventing extrarenal flares in 75 patients who were followed at a single center for 5 years for renal (71%) or nonrenal disease.⁵⁵ A substantial number of patients experienced flares during the second and third years of treatment, particularly in hematologic, mucocutaneous, and musculoskeletal domains. While awaiting additional data to define the efficacy of MMF in extrarenal lupus, the drug may be used in patients with moderately severe lupus who are intolerant or have not adequately responded to AZA.

Cyclosporin A

Pharmacology. Cyclosporin A (CsA), a fungus-derived calcineurin inhibitor that deactivates T cells, also reduces antigen presentation and autoantibody production by lupus B cells. Following oral administration, peak serum concentration occurs within 1 to 8 hours. Drug concentration is measured in whole blood, but this is rarely necessary in autoimmune diseases, unless CsA is used in doses greater than or equal to 3 mg/kg/day. Clinical response occurs 1 to 2 months after treatment initiation. Several drugs interact with CsA, leading to reduced (rifampin, phenytoin, phenobarbital, nafcillin) or increased (erythromycin, clarithromycin, azoles, calcium channel blockers, amiodarone, allopurinol, colchicine) drug concentrations. The drugs may also augment CsA nephrotoxic effects (NSAIDs, aminoglycosides, quinolones, angiotensin-converting enzyme [ACE] inhibitors, amphotericin B). Common adverse

events include mild gastrointestinal complaints, hirsutism, gingival hyperplasia, and mild elevation in serum alkaline phosphatase levels. Tremor, paresthesias, electrolyte disturbances (hyperkalemia and hypomagnesemia), and hyperuricemia may also occur. Hypertension occurs in nearly 20% of patients receiving CsA and is controlled by either reduction of the dose or antihypertensive treatment. A major adverse effect is nephrotoxicity, which is reversible after adjustment of the dose or drug discontinuation, and CsA should be avoided in patients with impaired renal function (see Table 81-1).

Use in Proliferative Lupus Nephritis. Uncontrolled studies have demonstrated efficacy of CsA when used in combination with GC or in between quarterly doses of IV-CYC in refractory-to-conventional treatment PLN. Beneficial effects include reduction in proteinuria, stabilization of renal function, improvement in overall disease activity, and a modest steroid-sparing effect. Rihova and colleagues⁵⁸ prospectively studied 31 LN patients ($n = 24$ with class III/IV nephritis) who were treated with CsA (5 mg/kg/day in two equal doses and then adjusted to trough level 80 to 120 ng/mL) and low-dose prednisone. After a mean of 7 months, all but two patients achieved complete response, defined as proteinuria less than 1 g/day and improved or stabilized renal function. About half of these patients, however, experienced a renal flare after CsA withdrawal.

Moroni and colleagues²⁹ compared AZA with CsA as maintenance therapies in 69 patients with diffuse PLN and preserved renal function. All patients received induction therapy with 3 daily pulses of 1 g IV-MP, followed by prednisone and oral CYC for 3 months. They were then assigned to receive either CsA (4 mg/kg/day for 1 month and then tapered to 2.5 to 3 mg/kg/day) or AZA (1.5 to 2 mg/kg/day) for 2 to 4 years. The two groups did not differ in flare-ups, proteinuria, and blood pressure levels. Both agents were well tolerated. In another study, 40 patients with newly diagnosed PLN and mild renal insufficiency were randomly assigned to sequential induction and maintenance therapy with either CYC or CsA.⁵⁹ The CYC regimen included 8 pulses IV-CYC (10 mg/kg) administered within 9 months, followed by 4 to 5 oral CYC boluses; CsA was given orally 4 to 5 mg/kg/day for 9 months and then tapered to 3.75 to 1.25 mg/kg/day within the next 9 months. Both groups received oral MP (0.8 mg/kg/day, then tapered). In the intention-to-treat analysis, 16 patients in the CYC group (76%) and 13 patients in the CsA group (68%) achieved complete or partial response at 9 months (induction phase). At the end of maintenance phase (18 months), the respective percentages were 52% for CYC and 95% for CsA. The trend for more favorable response in the CsA group was due to a higher proportion of patients achieving a 50% or greater decrease in proteinuria (38% in CYC group vs. 74% in CsA group). Despite its methodology flaws, this trial provides evidence for efficacy of CsA in mild to moderate proteinuric PLN with preserved renal function.

Use in Membranous Lupus Nephropathy. Balow and Austin³⁷ performed an RCT in 42 patients with MLN to compare prednisone alone or in combination with CsA or monthly pulses of IV-CYC. Remission rates at 1 year were 27% for prednisone, 60% for IV-CYC, and 83% for CsA. During follow-up, however, rates of nephrotic syndrome

relapse were 10-fold higher in the CsA than the IV-CYC group, suggesting that despite its effectiveness as induction therapy, CsA may require maintenance therapy to prevent relapses in MLN.

Use in Extrarenal Lupus. Uncontrolled studies of short duration have shown improvement in disease activity, anti-dsDNA titers, and cytopenias with modest GC reduction in SLE patients who received low-dose CsA.^{60,61} The BILAG group performed a multicenter, nonblinded RCT to compare the steroid-sparing effect of CsA (titrated to 2.5 to 3.5 mg/kg/day in two divided doses and adjusted to changes in SCr) versus AZA (2 to 2.5 mg/kg/day) in severe lupus requiring 15 or greater mg/day prednisone.⁶² Eighty-nine patients (66% whites) were randomized; 66% had active disease (defined as a BILAG A or B in any systems), and 34% entered the study because a different steroid-sparing agent was required. At 12 months, the unadjusted mean reduction in prednisolone dose was 9.5 ± 8.1 mg in the CsA group and 10.2 ± 6.2 mg in the AZA group. These improvements, however, were deemed as suboptimal for both drugs because almost 50% of patients with active disease at baseline failed to respond. The two groups did not differ in any of the secondary end points, namely disease activity, response to treatment, flares, damage accrual, and quality-of-life measures. In terms of safety, 23 patients (49%) who received CsA developed hypertension and another 6 patients (13%) showed a rise in SCr, both successfully managed by CsA dose reduction or addition of antihypertensive treatment. Thus CsA may be used as an alternative steroid-sparing agent to AZA in SLE patients, but with monitoring of the renal function and blood pressure.

Tacrolimus

Tacrolimus is a 10 to 100 times more potent calcineurin inhibitor than CsA. Systemic administration has been associated with dose-dependent reversible nephrotoxicity and blood pressure elevation, albeit less often than CsA. Other reported adverse effects include cardiomyopathy in children, anxiety, seizures, delirium and tremor, diabetes, and hyperlipidemia. In a pilot study of 10 SLE patients with skin and musculoskeletal disease, tacrolimus administered at doses of 1 to 3 mg/day for 1 year resulted in a significant reduction in SLE Disease Activity Index (SLEDAI) score and the dose of GC.⁶³ Tacrolimus has also demonstrated beneficial effects in refractory-to-conventional therapy PLN and LMN.⁶⁴⁻⁶⁶ Miyasaka and colleagues⁶⁷ conducted a placebo-controlled, double-blind trial in 63 patients with active mild-to-moderate nephritis requiring 10 or greater mg/day prednisone. They were randomized to receive a 28-week course of either tacrolimus (3 mg/day) or placebo in combination with GC (≤ 10 mg/day). In intention-to-treat analysis, only tacrolimus-treated patients had significant improvement in the author-defined nephritis disease activity index; 4 out of 27 patients in the tacrolimus group as compared with 1 out of 33 in the placebo group achieved proteinuria less than 0.3 g/day. Higher rates of GI toxicity and hyperglycemia were observed in the tacrolimus group.

Tacrolimus has been used in combination with MMF in severe or resistant LN. Cortés-Hernández and colleagues⁶⁸ prospectively studied 70 patients with moderately severe

PLN who received induction therapy with 3 daily pulses of IV-MP (1 g/dose) and oral MMF (2 g/day), in conjunction with oral prednisone (1 mg/kg/day for 4 weeks, then tapered). In case of renal flare or treatment failure despite an increase in MMF dose, oral tacrolimus (0.075 mg/kg/day, adjusted to trough level 5 to 10 ng/mL) was added. At the end of the 65-month follow-up, tacrolimus had been started in 17 patients (24%), with 12 of them achieving complete or partial response after an average of 24 months. Tacrolimus/MMF combination therapy (tacrolimus 4 mg/day, MMF 2 g/day) has also been compared against IV-CYC (6 to 9 pulses of 1 g/m²) in patients with mixed class IV + V LN.⁶⁹ In this study, patients had mean estimated GFR of 98 mL/min, proteinuria 4.4 g/day, and most had previously been treated with MMF or CYC. Both groups received 3 daily pulses of IV-MP (0.5 g/day) and then switched to oral prednisone. After 6 months, 10 patients in the “multitarget” group versus 1 patient in the IV-CYC group achieved complete remission. Combination therapy was well tolerated, and no major effects were observed. This is in contrast, however, with the significant toxicity reported in other patients with LN who received the same combination therapy.⁷⁰ Therefore additional studies with a larger number of patients and longer follow-up are necessary to establish the efficacy, safety, and specific indications of such a multidrug approach in LN.

Biologic Therapies

B Cell–Depleting Therapies

B cells play a key role in lupus pathogenesis by several means. First, they produce pathogenic autoantibodies that cause tissue damage by immune complex formation, complement activation, and direct cytotoxicity. They also function as antigen-presenting cells and secrete inflammatory cytokines that activate T cells.

Rituximab. Rituximab (RTX) is a chimeric mouse-human monoclonal antibody targeting the cell membrane protein CD20, which is expressed in all developmental stages of B cells, except for the hematopoietic stem cell and the plasma cell. Its mechanism of action involves cytotoxicity through complement activation, antibody-dependent cell-mediated cytotoxicity, and induction of apoptosis. RTX has been used in more than 450 SLE patients with refractory-to-cytotoxic therapy SLE, mainly as add-on therapy to GCs or other immunosuppressive agents, or both.^{71,72} Clinical response was noted in more than 80%, with manifestations such as neuropsychiatric disease,⁷³ PLN, and autoimmune cytopenias, showing higher response rates. Data from a French lupus registry including a total of 136 patients also indicated response rates of at least 70% for various manifestations, with autoimmune cytopenias exhibiting the most favorable outcomes (85% for hemolytic anemia, 92% for thrombocytopenia). A clinically significant decrease in SLEDAI by 3 or more units was observed in 71%.⁷⁴ With regard to LN, a meta-analysis of observational studies found an overall complete and partial response rate with RTX therapy of 69%, with lower rates observed in LMN.⁷⁵ Two European cohorts, however, have reported comparable response rates in patients with PLN and LMN who received RTX in combination with steroids and IV-CYC.⁷⁶

Unexpectedly, two RCTs failed to demonstrate efficacy of RTX in SLE. The EXPLORER trial assessed the effects of RTX over 52 weeks in patients with active moderate to severe extrarenal SLE.⁷⁷ A total of 257 patients were randomized to receive RTX or placebo (two biweekly infusions of 1000 mg at baseline and at 6 months), in combination with background immunosuppression (AZA, MMF, MTX) and prednisone at a dose of 0.5 to 1 mg/kg/day, not tapered until day 16 after the first RTX infusion. At week 52, no difference was observed between RTX and placebo in the primary (BILAG-defined major or partial clinical response) or any of the secondary end points. The LUNAR trial evaluated the efficacy of RTX versus placebo, both in combination with MMF (3 g/day), in 144 patients with active PLN.⁷⁸ By week 52, there was no significant difference between the two groups in terms of complete or partial renal response. Both studies were criticized for suboptimal design, mainly due to background therapies with high doses of oral GC and immunosuppressive drugs, which could have masked RTX effects. Alternatively, RTX may be more efficacious in patients with aggressive disease refractory to conventional treatment, as were most patients included in open-label trials.

RTX is generally well tolerated with mild infusion reactions being the most common adverse event, usually prevented by premedication with antihistamines and GCs. Mild infections are common (up to 20%), but the overall risk for serious or opportunistic infections is not significantly increased.⁷⁹ Following the report of a few cases of progressive multifocal leukoencephalopathy (PML) in RTX-treated patients with RA and SLE, the U.S. Food and Drug Administration (FDA) has issued an alert about possible RTX and PML links. More data are necessary to evaluate whether RTX indeed increases the inherent risk for PML in SLE. Together, although RTX cannot be considered first-line therapy for mild to moderate SLE, its use may be justified in severe refractory cases on the basis of mounting evidence from open-label trials. Accordingly, the American College of Rheumatology (ACR) and the EULAR–European Renal Association have included rituximab (anti-CD20 mAb) as a therapeutic option for selected cases of LN refractory to conventional immunosuppressive treatment.^{80a,80b}

Ocrelizumab. The BELONG trial evaluated the efficacy and safety of ocrelizumab (humanized anti-CD20 monoclonal antibody) versus placebo, both in combination with either MMF (up to 3 g/day) or IV-CYC (Euro-Lupus protocol) in 378 patients with PLN.⁸⁰ The study was prematurely terminated due to increased rates of serious and opportunistic infections in ocrelizumab-treated patients, both when combined with MMF and IV-CYC.

B Cell Inhibitors

Epratuzumab. Epratuzumab is a recombinant anti-CD22 monoclonal antibody that modulates lupus B cell function.⁸¹ CD22 is a membrane co-receptor for the B cell receptor mediating inhibitory signaling through attenuation of calcium efflux. In 14 SLE patients with moderately active disease, epratuzumab therapy resulted in reduction in BILAG scores by greater than or equal to 50% in more than 70% of patients at 6 weeks and in nearly 40% of patients at 18 weeks.⁸² Drug tolerability was acceptable, and mild

infections occurred in a minority of participants. Positive results have been announced for a phase IIb placebo-controlled, dose-defining trial in moderate to severe SLE. Using a composite BILAG-based response index, patients who received epratuzumab 600 mg weekly or 1200 mg biweekly achieved almost twofold higher response rates than the placebo group at the end of the 12-week treatment cycle. A similar rate of adverse events was recorded in the two groups.⁸³ Phase III trials in moderate and severe SLE are under way.

Belimumab. The B lymphocyte stimulator protein (BLyS, also known as B cell activation factor [BAFF]) and the proliferation-inducing ligand (APRIL) are growth factors important for B cell survival and maturation. BLyS binds to three different B cell receptors, namely the transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI), the B cell maturation antigen (BCMA), and the BAFF receptor (BAFF-R), whereas APRIL signals through TACI and BCMA.⁸⁴

Belimumab is a fully human anti-BLyS monoclonal antibody. An initial phase II trial of belimumab in combination with GCs and/or immunosuppressive agents in 449 active SLE patients did not meet its primary end points.⁸⁵ In a posthoc analysis, however, serologically active patients (ANA titer $\geq 1:80$ or anti-dsDNA positive) had a significantly higher response by week 52 in terms of SLEDAI and physician's global assessment. These two parameters were combined with BILAG to define a novel activity index, the SLE responder index (SRI), which revealed favorable response rates for belimumab.⁸⁶

Two subsequent phase III placebo-controlled RCTs (BLISS-52, BLISS-76) evaluated two different doses of belimumab (1 mg/kg, 10 mg/kg; dosed IV on days 0, 14, 28, and then every 28 days) on top of standard therapy in more than 1500 serologically positive SLE patients, using the SRI as the primary end point. Belimumab treatment resulted in a modest albeit significant reduction in disease activity and needs for additional GC, coupled with an increase in time-to-first flare.⁸⁷ In BLISS-52, 58% achieved the primary end point in the high-dose belimumab arm versus 44% in the placebo group; the respective figures in BLISS-76 were 43% for belimumab and 34% for placebo. There were no significant differences in infectious adverse events between the two drugs. These data opened the way for approval of this agent for the treatment of SLE.

Atacicept. Atacicept (TACI-Ig) is a recombinant fusion protein of the extracellular domain of TACI and the human IgG1Fc domain. TACI mediates signals from both BLyS and APRIL, thus affecting memory B cells, plasma cells, and immunoglobulin production. This was illustrated in two phase Ib placebo-controlled trials in patients with mild to moderate SLE.^{88,89} Both studies found no difference in adverse events between the two study groups, with the exception of mild injection-site reactions in patients receiving atacicept. However, a phase II/III trial of atacicept in combination with MMF in LN was prematurely terminated due to increased infection rates.

Co-stimulation Blockade

CD40-Ligand Blockade. CD40-ligand (CD40L) is expressed on activated T cells and stimulates antigen-

presenting cells including B cells through engagement with CD40. Anti-CD40L treatment resulted in improvement of renal disease and increased survival in NZB/W F1 lupus mice.⁹⁰ Two fully humanized monoclonal anti-CD40L antibodies have been developed for therapeutic trials in humans: BG9588 and IDEC-1310. The latter showed no efficacy in mild to moderate SLE.⁹¹ The encouraging results by the use of BG9588 (improvement in serologic activity and decrease in hematuria in 28 patients with PLN) were overpowered by the occurrence of serious thromboembolic events.⁹²

Abatacept. Abatacept (CTLA4-Ig) is a recombinant protein that comprises the extracellular domain of human CTLA-4 fused to the Fc portion of human IgG1 and antagonizes CD28-mediated T cells. It is approved for the treatment of moderate to severe RA and juvenile idiopathic arthritis. CTLA4-Ig delayed disease progression in lupus-prone mice, especially when combined with CYC.⁹³ A placebo-controlled, phase IIb trial of abatacept in combination with GC and background immunosuppressive therapy in 175 SLE patients with skin, joint, cardiovascular, and respiratory manifestations failed to meet its primary end point.⁹⁴ After 1 year, the proportion of patients with new BILAG A/B flare after steroid taper did not differ between the two groups. However, the trial design may have undermined potential efficacy of abatacept because patients were started on high doses of GC (30 mg/day) and tapering began on day 29 or 57. Posthoc analysis showed that patients with polyarthritis benefited more from abatacept treatment. Serious adverse events were significantly more frequent in the abatacept group (20% vs. 7% in placebo) including bronchitis, diverticulitis, and gastroenteritis. Two RCTs are currently under way to evaluate abatacept in combination with MMF or IV-CYC in LN.

Anticytokine Therapy

Tumor Necrosis Factor Inhibitors. Tumor necrosis factor (TNF) has divergent effects on the immune system in lupus. In an open-label study, seven SLE patients with moderately active disease received four doses of 300 mg infliximab on day 0 and at weeks 2, 6, and 10, in combination with AZA or MTX. Anti-dsDNA and other autoantibodies increased in most patients, peaking 4 to 10 weeks after the last infliximab infusion but returning to baseline levels thereafter.⁹⁵ In the prospective follow-up of 13 patients, 6 out of 9 patients with LN had a long-term (up to 5 years) response after four infusions of infliximab in combination with AZA.⁹⁶ All five patients with severe arthritis responded, but only for 2 months after the last infusion. Long-term therapy was associated with high rates of serious adverse events. In another small open-label study in resistant proliferative or membranous LN, treatment with infliximab in combination with oral prednisone and CsA resulted in transient reduction of proteinuria and stabilization of renal function.⁹⁷ Together, it is unlikely that TNF inhibition will be used routinely in SLE treatment.

Interferon Inhibition. Type I interferon (IFN- α) has been implicated in lupus pathogenesis through breakdown of immune tolerance. Serum IFN levels are increased and correlate with disease activity, and gene expression studies have identified an “interferon signature” in a subset of SLE patients.⁹⁸ A phase I trial evaluated the effects of a single

dose of anti-IFN- α monoclonal antibody (MEDI-545) in SLE.⁹⁹ It was noted to downregulate IFN-inducible genes and other signaling pathways such as GM-CSF, TNF, IL-10, IL-1 β , and BAFF. Two phase II trials are ongoing to assess safety and efficacy of anti-IFN therapy in lupus.

Anti-IL-6 Therapy. In lupus-prone mice, blockade of IL-6 or its receptor reduced anti-dsDNA levels, ameliorated proteinuria, and increased survival.¹⁰⁰ Tocilizumab, a humanized monoclonal antibody against the α -chain of the IL-6 receptor, has shown efficacy in RA. Illei and colleagues¹⁰¹ tested tocilizumab in 16 patients with moderately active SLE, in combination with low-dose GC. Patients received tocilizumab (2, 4, 8 mg/kg) biweekly for 12 weeks and were monitored for an additional 8 weeks. Results revealed a correlation between clinical and serologic efficacy, evidenced by reduction in SLAM and SLEDAI indices, acute-phase reactants, and anti-dsDNA levels. Dose-dependent neutropenia (median decrease in neutrophil count by 56% in the 8 mg/kg group) and frequent infections (upper respiratory and urinary tract) were observed. To resolve issues on efficacy and safety, a larger trial is necessary.

Anti-IL-10 Therapy. IL-10 is upregulated in SLE and correlates with disease activity, although its exact pathogenic role has not been elucidated. An open-label trial in six steroid-dependent SLE patients showed improvement in disease activity reported up to 6 months after the administration of an anti-IL-10 murine monoclonal antibody (BN10) for 21 days.¹⁰² However, all patients developed antibodies against BN10, and new trials are awaited with a human anti-IL-10 monoclonal antibody.

Other Therapies

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) exerts immunosuppressive effects by interaction with anti-idiotypic antibodies, interference with the complement and cytokines, cytolysis of target cells, induction of apoptosis through Fc receptors, and modulation of co-stimulatory molecules.¹⁰³ In an RCT of 14 patients, IVIG (400 mg/kg for 5 consecutive days monthly for 18 months) was as effective as pulse IV-CYC (1 g/m² every 2 months for 6 months, then every 3 months for 1 year) as maintenance therapy of PLN.¹⁰⁴ In another study, high-dose IVIG (2 g/kg divided over 5 days) in 1 to 8 monthly courses was administered in 20 SLE patients with cytopenias, massive proteinuria, arthritis, fever, arthralgia, mood changes, and psychosis. IVIG therapy resulted in improvement in SLEDAI and dose of GC.¹⁰⁵ Common adverse events include fever, myalgia, headache, and arthralgia; less common are aseptic meningitis, nephropathy in patients who receive sucrose-containing preparations, and thromboembolic complications in older patients with atherosclerotic risk factors. The drug is contraindicated in IgA deficiency.

Synthetic Tolerogens

Tolerogenic peptides aim at restoring immune tolerance in lupus. Abetimus sodium (LJP-394) contains four identical dsDNA strands covalently linked to a small molecule

platform. It is thought to reduce anti-dsDNA antibodies by binding and clearance of soluble anti-dsDNA antibodies and B cell receptor cross-linking on dsDNA-specific B cells. Initial studies showed decrease of anti-dsDNA levels, prolongation of the time-to-renal flare, and reduced renal flares, especially in patients with high-affinity anti-dsDNA antibodies.¹⁰⁶⁻¹⁰⁸ However, a phase III placebo-controlled trial in 317 LN patients failed to meet its primary end point (prolongation of time to renal flare), although abetimus-treated patients had 21% fewer flares, reduced proteinuria, and improved SLEDAI scores.¹⁰⁹ The drug was well tolerated, and a 900-mg dosage was introduced in another trial, with no additional benefit.¹¹⁰ The spliceosomal peptide P140 is another tolerogen that has demonstrated benefit in early SLE trials. In a dose-escalation study in 20 patients with moderate SLE, the drug significantly decreased anti-dsDNA levels and slightly reduced SLEDAI.¹¹¹ The results of an ongoing phase IIb trial using SRI as efficacy index are awaited.

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a naturally occurring inactive steroid in adrenal glands, testes, and ovaries. Seven RCTs including a total of 842 patients have been performed to assess efficacy and safety of DHEA in SLE. Their meta-analysis showed that the drug had modest clinical effect only in mild to moderate disease.¹¹² DHEA treatment also resulted in improvement in health-related quality of life measurements.

Clofazimine

Clofazimine (CFZ) (100 mg/day), an antimicrobial used in the treatment of leprosy, has shown efficacy in the treatment of skin involvement in lupus.¹¹³ However, it should be reserved for patients with exclusively cutaneous disease because it may provoke severe lupus flares.

MANAGEMENT OF SPECIFIC SYSTEMIC LUPUS ERYTHEMATOSUS MANIFESTATIONS AND TREATMENT ALGORITHMS

KEY POINTS

Skin manifestations in SLE usually respond to sun exposure prophylaxis, topical glucocorticoids, and systemic antimalarials.

Risk stratification based on renal pathology, demographic, and clinical and laboratory characteristics enables the identification of LN patients at high risk for renal dysfunction who may benefit from aggressive cytotoxic therapy.

In moderately severe PLN, mycophenolate mofetil may be preferred as induction regimen, especially when gonadal toxicity is a concern. Failure to achieve response after the initial 6 months of therapy should evoke decisions about intensifying or altering immunosuppressive therapy.

Combination of monthly pulses of intravenous CYC and pulse intravenous methylprednisolone is the treatment of choice for severe LN. If substantial improvement occurs after the first 6 months, maintenance therapy with azathioprine or mycophenolate mofetil may be started.

Glucocorticoids alone or in combination with immunosuppressive agents are recommended for neuropsychiatric events felt to reflect an immune/inflammatory process; antiplatelet and/or anticoagulation therapy is recommended for events related to antiphospholipid antibodies.

Antiplatelet or anticoagulation therapies, or both, are necessary in patients with antiphospholipid syndrome to prevent recurrent events, but the intensity of such therapies remains controversial.

Mucocutaneous and Joint Disease

No single therapeutic agent has been officially approved for cutaneous lupus erythematosus (CLE). Mild malar rash and other photosensitive rashes usually respond to prophylaxis from sun exposure, but the use of sunscreens with high sun protection factor cannot be overemphasized. Topical GCs reduce redness and scaling. In an RCT of 78 patients with discoid lupus erythematosus (DLE), high-potency topical fluocinonide 0.05% was more effective than low-potency hydrocortisone 1% (response rates 27% vs. 10%, respectively).¹¹⁴ Calcineurin inhibitors (tacrolimus, pimecrolimus) are a useful alternative, especially for the face, because they cause less atrophic and rosacea-like effects than topical steroids.

In refractory to topical therapy skin disease, systemic antimalarials may be used alone or in combination with oral GCs (up to 20 mg/day). HCQ was equally effective and had more favorable safety profile than the oral retinoid acitretin in an RCT of 58 DLE patients.¹¹⁵ Other systemic treatment remains largely empiric. MTX has shown efficacy in refractory subacute CLE and DLE.¹¹⁶ Alternative choices include retinoids, dapsone, MMF, and IV-CYC.³⁹ Thalidomide and IVIG should be reserved for patients with severe recalcitrant CLE due to potential serious neurotoxicity and high cost, respectively (Figure 81-1).^{117,118}

Lupus arthritis follows the pattern of nonerosive symmetric polyarthritis primarily affecting the small joints of the hands and feet. In mild arthritis, initial therapy should be based on antimalarials. In persistent or aggressive disease, utilization of DMARDs is advocated. In a prospective controlled study, SLEDAI scores, need for steroids, and articular involvement were significantly improved in SLE patients receiving MTX for 6 months.¹¹⁹ Leflunomide is used less often. Anti-TNF agents have been implicated for anti-dsDNA antibody development or even drug-induced lupus. RTX may be used in severe lupus arthritis refractory to DMARDs.

Lupus Nephritis

Induction Therapy

Current therapeutic strategies in LN include an initial induction phase aimed at substantially improving disease

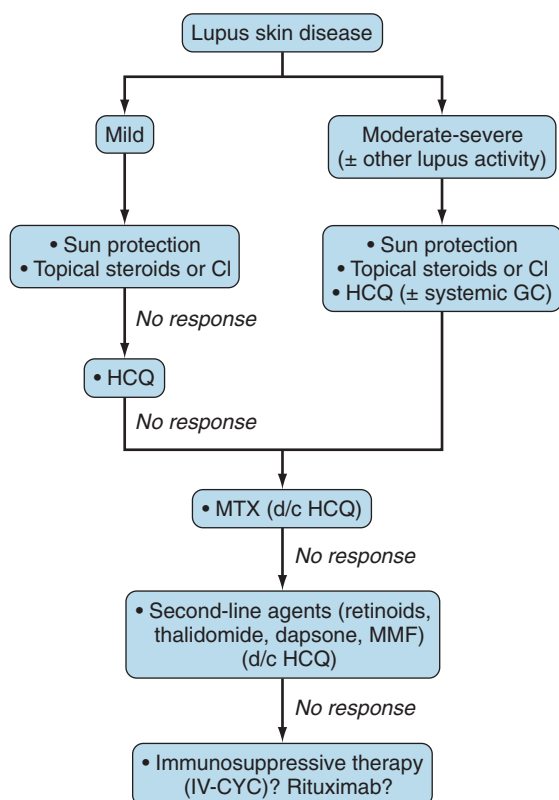

Figure 81-1 Suggested algorithm for the management of cutaneous manifestations in SLE. (See text for details.) CI, calcineurin inhibitors; d/c, discontinue; GC, glucocorticoids; HCQ, hydroxychloroquine; IV-CYC, pulse intravenous cyclophosphamide; MMF, mycophenolate mofetil; MTX, methotrexate. (Modified from Kuhn A, Ruland V, Bonsmann G: Cutaneous lupus erythematosus: update of therapeutic options: Part II, *J Am Acad Dermatol* 65:e195–213, 2010; and Kuhn A, Ruland V, Bonsmann G: Cutaneous lupus erythematosus: update of therapeutic options: Part I, *J Am Acad Dermatol* 65:e179–193, 2010.)

activity (or even attaining remission), followed by a *main-tenance* phase, in which the goal is to maximize the therapeutic effect and consolidate the response. Risk stratification, according to renal pathology¹²⁰ and patient demographic, clinical and laboratory characteristics, enables the identification of patients at risk for renal dysfunction or ESRD, or both, who may benefit from aggressive cytotoxic therapy (Table 81-5).^{8,121}

For *mild* class I/II disease, a limited trial of prednisone (0.5 to 1 mg/kg/day for 4 to 6 weeks and then tapered to alternate day 0.125 to 0.25 mg/kg if remission occurs) is indicated. The use of three consecutive daily pulses of IV-MP may expedite remission and allow for the use of lower GC doses (0.5 mg/kg/day). Addition of immunosuppressive therapy (AZA 1 to 2 mg/kg/day) either from the beginning or during GC tapering may decrease cumulative steroid dose. If the patient does not achieve complete remission (clearing of cellular casts and proteinuria, normalization of complement, minimal lupus activity) within 3 months or if nephritis worsens, therapy with MMF or monthly pulse IV-CYC should be initiated. Delay in immunosuppressive therapy because of a partial response beyond the 3 to 4 months may have an adverse impact on response to therapy, thus increasing the risk for flare.

Table 81-5 Severity of Lupus Nephritis

Proliferative Nephritis	
Mild	Class III nephritis without severe histologic features (crescents, fibrinoid necrosis); low chronicity index (≤ 3); normal renal function; non-nephrotic range proteinuria
Moderately severe	Mild disease as defined above with partial or no response after the initial induction therapy, or delayed remission (>12 mo), or Focal proliferative nephritis with adverse histologic features or reproducible SCr increase $\geq 30\%$, or Class IV nephritis without adverse histologic features
Severe	Moderately severe as defined above but not remitting after 6–12 mo of therapy, or Proliferative disease with impaired renal function and fibrinoid necrosis or crescents in $>25\%$ of glomeruli, or Mixed membranous and proliferative nephritis, or Proliferative nephritis with high chronicity alone (chronicity index >4) or in combination with high activity (chronicity index >3 and activity index >10), or Rapidly progressive glomerulonephritis (doubling of SCr within 2–3 mo)
Membranous Nephropathy	
Mild	Non-nephrotic range proteinuria with normal renal function
Moderate	Nephrotic range proteinuria with normal renal function at presentation
Severe	Nephrotic range proteinuria with impaired renal function at presentation ($\geq 30\%$ increase in SCr)

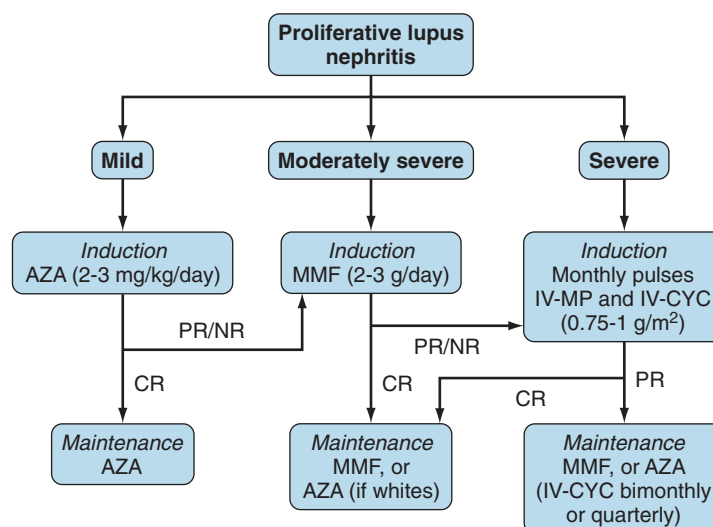

*Concomitant therapy with corticosteroids or immunosuppressive drugs, or both, may modify urinary sediment and histologic findings and should be taken into consideration.

SCr, serum creatinine.

In *moderately severe* PLN, meta-analyses of RCTs comparing MMF with CYC confirmed the efficacy of the former for induction therapy; claims of superiority toward CYC were not substantiated. MMF is increasingly used as a first-line treatment for most PLN cases due to its favorable toxicity profile, whereas CYC is reserved for the most severe ones. For whites, the low-dose (Euro-Lupus) IV-CYC regimen may be equally efficacious and less toxic than the high-dose (NIH) regimen. Both earlier¹²² and recent^{36,123,124} studies underscore the significance of early response to therapy at 6 months (defined as a decrease in SCr level and proteinuria <1 g/day) as a strong predictor of good long-term renal outcome. Thus failure to achieve response after the initial 6 months of therapy should precipitate decisions about switching from MMF to pulse IV-CYC.

In *severe* LN, the authors recommend induction therapy with 7 monthly pulses of IV-CYC in combination with 3 initial pulses of IV-MP at the start, followed by pulses of IV-MP in combination with IV-CYC at monthly intervals (1 pulse/month) for the first 6 to 12 months (see Table 81-3). High doses of prednisone (0.5 to 1 mg/kg/day tapered after 4 weeks) should be continued during the induction period. Addition of plasma exchange is of no benefit in terms of survival. For patients strongly opposing pulses of IV-CYC, alternative induction regimens include (1) daily oral MMF (1 g twice a day for 12 months with increase to 3 g/day if no response in 6 to 8 weeks) or (2) monthly pulses of IV-MP (1 g/m² daily) for three doses and then at monthly

Figure 81-2 Recommended treatment of proliferative lupus nephritis. Renal response is assessed at 6 months. Complete response (CR) is defined as decrease in proteinuria to less than 1 g/day (or <0.3 g/day if nephritis was diagnosed in the past 6 months) with normal serum albumin concentrations; inactive urine sediment; and improved or stable renal function. Partial response (PR) is defined as significant change in proteinuria (if nephrotic at baseline $\geq 50\%$ decrease in proteinuria to <3 g/day; if non-nephrotic at baseline but not meeting the CR criteria) and improved or stable renal function. All induction regimens include pulse intravenous methylprednisolone (IV-MP) (1 g/pulse \times 3) followed by oral prednisone (0.5 to 0.6 mg/kg for the first 4 weeks of induction, then tapered). AZA, azathioprine; IV-CYC, intravenous cyclophosphamide; MMF, mycophenolate mofetil; NR, no response.

intervals for 6 to 12 months if there is steady progress to remission. Adherence to the National Kidney Foundation–Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) guidelines for the management of renal diseases is of utmost importance. [Figure 81-2](#) summarizes the treatment recommendations for PLN.¹²⁵

Maintenance Therapy

Following induction of remission, patients with mild to moderate disease may be treated with low-dose GC (7.5 to 15 mg prednisone on alternate day) or AZA, with CsA being an alternative agent. For maintenance therapy in moderately severe disease, MMF or AZA could be used on the basis of availability and potential for pregnancy because MMF is associated with an increased risk of spontaneous abortion and fetal malformation. Because of the significant difference in the cost between the two drugs, patients with less severe LN could first be treated with AZA, especially white individuals.

In severe disease, our preferred approach is quarterly pulse IV-CYC until 1 year beyond remission. If substantial improvement occurs, this could be followed by AZA or MMF after the first 6 months. Microscopic hematuria or non-nephrotic proteinuria may not clear for several months, even when most other clinical parameters have remitted. Remission may occur at an average of 1.5 to 2 years after therapy. Thus discontinuing pulse IV-CYC therapy because of lack of achieving remission before completing at least 2 years of treatment is not justified unless there is definite disease worsening (reproducible increase in SCr and/or >50% increase in proteinuria at the nephrotic range). In selected patients with severe disease who have achieved remission, MMF may be used as a maintenance regimen (see [Figure 81-2](#)).¹²⁶

Lupus Membranous Nephropathy

LMN with mesangial expansion (pure membranous) and low-grade proteinuria (<2 g/day) carries a low risk for progression to ESRD (20% at 10 years) and may require

renin-angiotensin axis blockade and low-dose GC. Persistent nephrotic-range proteinuria, abnormal renal function, and black race have been implicated as high-risk features and are indications for immunosuppressive therapy.¹²⁷ Uncontrolled studies indicate beneficial effects of the combination of GC with AZA or calcineurin inhibitors in mild to moderate LMN.^{65,128} In the RCT of Austin and colleagues³⁷ oral CsA and pulse IV-CYC were equally successful in inducing remission. Nephrotic syndrome relapses were more common in the CsA group, suggesting that these patients should receive maintenance therapy with lower CsA doses or other immunosuppressive agent. MMF has emerged as an efficacious regimen with more favorable safety profile for both induction and maintenance therapy of class V LN on the basis of the pooled data from two RCTs comparing MMF versus IV-CYC in moderately severe LN.⁵⁰ However, this will have to be proven in larger trials with longer follow-up. Mixed membranous and proliferative histology (especially when diffuse proliferation is present) has a worse prognosis, even from pure proliferative disease. These patients should be aggressively treated as those with PLN. Bao and colleagues⁶⁹ have reported interesting results using the combination of prednisone, MMF, and tacrolimus as induction therapy for mixed class IV+V LN. In this trial, multitarget therapy was associated with higher rates of complete response compared with pulse IV-CYC. These results need to be confirmed before adopting this regimen.

Treatment of Renal Flares

Approximately 30% to 50% of patients with moderate to severe PLN will relapse after achieving partial or complete remission.¹²⁹⁻¹³¹ Nephritic flares are characterized by active urine sediment and reproducible increase of SCr ($\geq 30\%$ increase) and may adversely affect renal prognosis; proteinuric flares without significant changes in renal function have a more benign prognosis.^{131,132} Risk factors for progression to ESRD after a nephritic flare are patients with marked loss of renal function (SCr >2 mg/dL) at the time of response, partial response to therapy, and high chronicity and activity

indices at renal biopsy. Flares are more common in African-American patients and patients with undetectable serum C3/C4 levels. However, pre-emptive treatment in the face of abnormal serology (rising anti-dsDNA or reduced C3/C4 titers, or both) may result in overtreating a large number of patients. Mild to moderate flares (stable SCr, subnephrotic proteinuria) may be treated with GC in combination with AZA or MMF. Calcineurin inhibitors (alone or added to existing immunosuppressive therapy) have also demonstrated efficacy. For severe nephritic flares, reinstitution of cytotoxic therapy with monthly pulses of IV-CYC and IV-MP is the authors' preferred approach, with MMF considered as an alternative agent. RTX has also been successfully used in a small case series.

Central Nervous System Disease

Less than 40% of neuropsychiatric events in SLE patients can be attributed to lupus, whereas the remaining cases represent complications of the disease or its therapy, or they may be caused by infections, metabolic abnormalities, and drug adverse effects. Neuropsychiatric SLE (NPSLE) is a clinical challenge, and difficulties include the correct attribution of neuropsychiatric syndromes to SLE, the selection of proper diagnostic examinations, and optimal treatment. To facilitate the management of these patients, EULAR has published recommendations using an evidence-based approach followed by expert consensus (Table 81-6).¹³³ All nonlupus contributing factors should be

identified and treated, and symptomatic therapy should be considered if appropriate. Moderate to high doses of GCs alone or in combination with immunosuppressive therapy (AZA for mild to moderate cases, IV-CYC for severe ones) may be used for neuropsychiatric events felt to reflect an immune/inflammatory process (particularly acute confusional state, aseptic meningitis, myelitis, optic neuritis, refractory seizure disorder, peripheral neuropathies, psychosis) or when they occur in the context of active generalized lupus, following exclusion of non-SLE-related causes.⁴⁰ Although a placebo-controlled trial reported improved cognition in five out of eight SLE patients with inactive disease and mild cognitive dysfunction who were treated with low-dose prednisone (0.5 mg/kg/day for 21 days, then tapered), GCs should not be routinely administered in these patients unless to control concurrent SLE or other overt NPSLE activity. In severe NPSLE refractory to cytotoxic therapy, the use of plasma exchange, IVIG, and RTX has been reported in uncontrolled studies, with varying rates of success. Antiplatelet or anticoagulation therapy are recommended for NPSLE related to aPL antibodies, especially for thrombotic cerebrovascular disease (see Antiphospholipid Syndrome later).

Hematologic Disease

Peripheral cytopenias are common but usually mild in SLE. A thorough clinical and laboratory evaluation is necessary to exclude offending drugs or other secondary causes. Mild

Table 81-6 Approach to Systemic Lupus Erythematosus (SLE) Patients with Neuropsychiatric Manifestations

What Are the Risk Factors for NPSLE?
Generalized (non-CNS) lupus activity or damage, previous or other concurrent major NPSLE manifestation(s), persistently positive moderate-to-high titers of aPL antibodies
When to Suspect NPSLE
Any SLE patient at risk who presents with new-onset neurologic or psychiatric manifestations without an apparent cause In patients with subtle or mild signs or symptoms, a high index of suspicion is required to exclude underlying overt NPSLE
Is It NPSLE?
Mild manifestations (headache, mood disorders, anxiety, mild cognitive dysfunction, polyneuropathy without electrophysiologic confirmation) are common (up to 40%) but are not usually related to lupus Non-SLE-related causes (infections, metabolic disturbances, drug adverse effects) must be excluded Most (40%-50%) lupus-related events occur at onset or during the first 2-4 yr after SLE diagnosis, common (50%-60%) in the presence of generalized lupus activity Attribution to lupus more likely when NPSLE risk factors are present
What Diagnostic Workup Is Indicated?
Magnetic resonance imaging is the preferred neuroimaging test and may help to identify: Ischemic/thrombotic, demyelinating, or infectious processes T2-weighted white matter lesions: in the absence of other confounding factors (increased age, long-standing SLE, atherosclerotic risk factors, heart valve disease) may reflect underlying CNS lupus activity (especially when ≥ 5 in number, ≥ 8 mm in size, bihemispheric) Cerebrospinal fluid analysis should be performed when CNS infection is suspected; mild abnormalities common in active NPSLE Other tests as indicated: electroencephalogram to diagnose seizure disorder, neuropsychologic tests to assess cognitive dysfunction, nerve conduction studies for peripheral neuropathy
What Is the Treatment of NPSLE?
Control aggravating factors (infection, dehydration, metabolic abnormalities, hypertension) Control symptoms (anticonvulsants, antidepressants, antipsychotics) Glucocorticoids and/or immunosuppressive therapy in cases of: Acute confusional state, aseptic meningitis, myelitis, optic neuritis, refractory seizure disorder, peripheral neuropathies, severe psychosis Control generalized (non-CNS) lupus activity Antithrombotic or antiplatelet therapy aPL-associated NPSLE (particularly cerebrovascular disease, ischemic optic neuropathy, chorea) or when antiphospholipid syndrome-associated thrombotic events are present

CNS, central nervous system; NPSLE, neuropsychiatric systemic lupus erythematosus.

cytopenias require no specific therapy other than regular monitoring. In more severe cases (platelet count $< 50 \times 10^3/\text{mm}^3$ or active bleeding, neutrophil count $< 1000/\text{mm}^3$), GCs (1 mg/kg/day with gradual tapering) are the mainstay of treatment.¹³⁴ Pulses of IV-MP followed by lower doses of prednisone (0.6 mg/kg/day) may be used alternatively. Steroid-sparing agents (AZA, CsA) can be added during steroid tapering.⁶¹ Patients with steroid-resistant thrombocytopenia may be candidates for splenectomy, especially when there is no significant lupus activity in other organs. Early reports from the 1980s have shown a satisfactory response to splenectomy with progressive rise in platelet counts. Prophylactic measures for avoidance of infectious complications in patients undergoing splenectomy are mandatory. These include immunization against encapsulated bacteria (*Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*) and influenza virus, as well as prophylactic antibiotic coverage when necessary.

Resistant life-threatening cytopenias may require potent immunosuppressive therapy. Monthly pulses of IV-CYC have been shown to reverse severe refractory autoimmune thrombocytopenia.¹³⁵ In severe neutropenia, however, the risk for potential leukocyte toxicity of CYC should be considered. The use of lower-dose IV-CYC (Euro-Lupus protocol) is associated with a better safety profile and is advocated by some centers. RTX may be considered in patients with refractory neutropenias, especially when the use of IV-CYC is hampered by its potential myelotoxicity.^{72,74} Of note, RTX may also be associated with both early- and late-onset neutropenia, which is usually self-limited.¹³⁶

Treatment of immune thrombocytopenia may sail into a new era with the development of novel thrombopoietin mimetic agents that enhance platelet production. Two such agents, romiplostim and eltrombopag, were shown to be superior than standard of care in large RCTs and have been approved for the treatment of immune thrombocytopenia.^{137,138} They resulted in a greater incidence of sustained platelet response, less bleeding, fewer transfusions, reduced requirement for other treatments (including splenectomy), and greater improvement in quality of life. Adverse events were minimal. The ultimate place these remedies will take in the armamentarium against immune thrombocytopenia (before or after splenectomy) will depend on their long-term efficacy/safety profile and their cost compared with the potentially curative and relatively safe choice of splenectomy.

Supportive treatment may be necessary for severe cytopenias or associated complications. Febrile neutropenia should be treated with broad-spectrum antibiotics and, if neutrophil counts are less than $500/\text{mm}^3$, with human G-CSF. Serious hemolytic anemia (Hb < 7 g/dL) may require red blood cell transfusions, whereas platelet transfusions are best avoided unless invasive procedures are planned.

Antiphospholipid Syndrome

aPL antibodies (anticardiolipin [aCL], anti- β_2 -glycoprotein I [anti- β_2 GPI], and lupus anticoagulant [LAC]) are encountered in 30% to 40% of SLE and are associated with increased risk for thrombo-occlusive incidents. The combination of vascular thrombosis or obstetric morbidity, or both, and persistently positive aPL antibodies measured at

least 12 weeks apart, defines antiphospholipid syndrome (APS).^{139,140}

Thrombotic Antiphospholipid Syndrome

APS-associated thrombosis requires antiplatelet and/or anticoagulation therapy to prevent recurrent events, but the intensity of such therapies remains controversial. On the basis of the results of two systematic reviews,^{141,142} patients with definite APS and first venous or arterial noncerebral/noncoronary thrombosis should receive oral anticoagulation (warfarin) at a target international normalized ratio (INR) 2 to 3, although some experts recommend higher-intensity anticoagulation following arterial thrombotic events.¹³⁹ Data from the Antiphospholipid Antibodies and Stroke Study (APASS) and large RCTs in the general population suggest that antithrombotic therapy is not superior to antiplatelet therapy for secondary thromboprophylaxis after noncardioembolic stroke or transient ischemic attack.¹⁴³ Because many patients studied were elderly and had low titers of aPL antibodies, determined at a single time point, the conclusions may be limited to these populations. Acute coronary artery syndromes should be treated according to the evidence base for the general population. For patients with recurrent thrombotic events, anticoagulation should target INR 3 to 4, especially if they have high-risk aPL profile (LAC or aCL IgG at higher titers, or anti- β_2 GPI plus LAC or aCL).¹⁴⁴ Additional atherothrombotic risk factors should be aggressively controlled. The role of newer classes of anticoagulants (direct thrombin inhibitors, oral direct factor Xa inhibitors)—currently licensed for the management of venous thromboembolism in the general population—for secondary APS thromboprophylaxis remains to be determined.

HCQ, in addition to its anti-inflammatory effects, has been proposed to exert antithrombotic properties through inhibiting platelet aggregation and arachidonic acid release from stimulated platelets. Use of HCQ has been associated with reduced rates of thrombosis in both aPL-positive and aPL-negative patients.¹⁴⁵ A systematic review of epidemiologic studies found evidence for antithrombotic effect of HCQ in SLE patients, especially in studies accounting for exposure previous to the event.²⁰ These results have not been confirmed in large prospective cohort studies,¹⁴⁶ and controlled studies are necessary to determine the effectiveness of HCQ for primary thromboprophylaxis. RCTs have also shown a protective effect of rosuvastatin (20 mg/day) against thrombosis (including cardiovascular events and venous thromboembolism) in healthy adults with normal low-density lipoprotein levels and elevated C-reactive protein (> 2 mg/dL).^{147,148} These findings justify the conduction of clinical trials of statins in aPL-positive patients. In small case series, RTX has demonstrated beneficial effects in severe APS cases including resolution of symptoms (especially thrombocytopenia) and reduction in aPL antibody titers.¹⁴⁹

Pregnancy in Antiphospholipid Syndrome

Pregnant SLE-APS patients are at increased risk for complications including maternal thrombosis, recurrent spontaneous abortions before 10 weeks' gestation, and late

adverse pregnancy outcomes such as fetal death, pre-eclampsia, fetal growth restriction, and preterm birth.^{150,151} For women with APS and a history of pregnancy complications or thrombosis, or both, a meta-analysis of three RCTs concluded that the combination of unfractionated heparin and aspirin confers a significant benefit in live births (odds ratio [OR] for first trimester loss, 0.26; number needed to treat [NNT], 4).¹⁵² The pooled effect of low-molecular-weight heparin was also favorable (OR 0.70) but not statistically significant. Conversely, combination therapy of either unfractionated or low-molecular-weight heparin with aspirin had no effect in prevention of late-pregnancy losses. Results from RCTs do not specifically define optimum treatment for women with fetal death (>10 weeks' gestation) or previous early delivery (<34 weeks' gestation) because of severe pre-eclampsia or placental insufficiency. Nonetheless, most experts recommend low-dose aspirin and either prophylactic or intermediate-dose heparin. A beneficial effect of low-dose aspirin in primary prevention of thrombotic events and miscarriage in SLE with persistently positive moderate to high titers of aPL antibodies has been suggested by some,^{145,153} but not all,¹⁵⁴ studies. Neither aspirin combined with low-molecular-weight heparin nor aspirin alone improved the live birth rate, as compared with placebo, among women with unexplained recurrent miscarriage.¹⁵⁵

Vitamin K antagonists are teratogenic and should be avoided between 6 and 12 weeks of gestation; even after 12 weeks of gestation they should be used cautiously due to increased risk for fatal bleeding. Antithrombotic coverage of the postpartum period is recommended for all APS patients irrespective of their thrombotic history. Women with previous thrombosis will need long-term anticoagulation, and treatment is generally switched to warfarin as soon as the patient is clinically stable after delivery.^{139,156} In patients with no previous thrombosis, the recommendation is prophylactic-dose heparin or low-molecular-weight heparin therapy for 4 to 6 weeks after delivery, although warfarin is an option. Both heparin and warfarin are safe during breastfeeding.

Other Antiphospholipid Syndrome Manifestations

A distinct type of small-vessel vaso-occlusive nephropathy with histologic features of thrombotic microangiopathy and chronic vascular lesions, termed APS *nephropathy*, should be suspected in aPL-positive patients with hypertension, proteinuria (usually mild to moderate), hematuria, and renal impairment.^{157,158} These patients may benefit from aggressive immunosuppressive therapy along with anticoagulation, but development of ESRD is common.¹⁵⁹ A minority of patients (<1%) can suffer from a potentially life-threatening variant of APS, catastrophic APS (CAPS), which is characterized by multiple small-vessel thromboses resulting in multiorgan failure.¹⁶⁰ Approximately 70% of patients manifest renal involvement, usually resulting in severe hypertension, proteinuria, hematuria, and renal impairment. The condition is associated with 50% mortality rate and may be treated with combination of anticoagulation and immunosuppressive therapy (high-dose GC alone or in combination with CYC) plus attempts to reduce aPL titers (plasma exchange, IVIG).

ADDITIONAL ISSUES

KEY POINTS

Pregnancy outcome in SLE is optimal when disease is clinically quiescent for at least 6 months.

The risks of treatment during pregnancy must be weighed against the risks of an untreated SLE flare, with potential deleterious effects on the mother and the fetus.

The treatment of pediatric-onset SLE is similar to that in adult SLE patients.

Treatment of Refractory Systemic Lupus Erythematosus

IV-CYC in combination with IV-MP has long been considered the treatment of choice for most patients with severe, life-threatening lupus. Mounting evidence from uncontrolled studies supports the beneficial effects of RTX (alone or in combination with IV-CYC) in refractory SLE.¹⁶¹⁻¹⁶³ Higher response rates have been reported for skin, blood, central nervous system (CNS), and renal manifestations.⁷⁴ Advantages from the use of RTX include its favorable toxicity profile and the rapid onset of action.⁷³ MMF may rescue a few refractory SLE patients including LN cases with inadequate response to CYC. However, its efficacy in critically ill patients requires further documentation. Calcineurin inhibitors have also shown efficacy in resistant-to-standard immunosuppressive therapy lupus,¹⁶⁴ particularly LN,¹⁶⁵ and benefits of combination therapy with MMF were reported in a small RCT.⁶⁹ For selected patients with CNS involvement, autoimmune thrombocytopenia, or APS, IVIG may be considered as an adjunct therapy. Synchronized therapy with plasmapheresis and pulse IV-CYC has been used in severe PLN cases.¹⁶⁶

High-dose chemotherapy with autologous hematopoietic stem cell transplantation (HSCT) has been used in SLE.¹⁶⁷ The rationale is to maximally suppress the immune system with an immunoablative regimen (usually high-dose CYC combined with equine antithymocyte globulin and pulse IV-MP) and then rescue the patient from prolonged cytopenias by the infusion of mobilized CD34-enriched stem cells. A few patients who received HSCT experienced improvement in disease activity, but relapses were common.¹⁶⁸ In a pilot study, 15 patients refractory to conventional treatment ($n = 14$ with nephritis) received a small dose of allogeneic bone marrow-derived mesenchymal stem cells ($1 \times 10^6/\text{kg}$ by IV injection).¹⁶⁹ Prednisolone was tapered from week 2 onwards, and IV-CYC was continued with larger intervals. Rapid and sustained improvements in autoantibody levels, proteinuria, and nonrenal manifestations were reported, with no significant acute toxicity. Until more data are available, stem cell transplantation remains an experimental procedure that needs to be considered in critically ill lupus patients, ideally in experienced centers.

Treatment of Lupus in Pregnancy

Pregnancy may increase disease activity and precipitate the appearance of flares (13% to 74%), which are usually mild.

Lupus pregnancies are considered high risk for maternal and fetal complications. A recent meta-analysis reviewing 2571 pregnancies in SLE patients reported unsuccessful pregnancy and preterm birth rates of 23% and 39%, respectively, while maternal complications included nephritis (16%), hypertension (16%), and pre-eclampsia (7%).¹⁵¹ A history of LN and the presence of aPL antibodies were associated with development of hypertension and premature birth.

The management of a pregnant woman with an SLE flare is challenging and should be dealt with on a multidisciplinary basis (Table 81-7). The risks of treatment with potential deleterious effects on the mother and the fetus must be balanced against the risks of untreated disease. Mild flares involving the skin, joints, and blood are usually treated with GC. The latter are relatively safe, although they carry a small risk of harm (increased risk of cleft palate in children, intrauterine growth retardation, maternal hypertension, diabetes) and thus should be used in the lowest enough doses to control disease activity. HCQ has a good safety record despite crossing the placenta. AZA, although listed as FDA category D, can be used with caution as a steroid-sparing agent. The same holds true for CsA (category C). In contrast, CYC is a major teratogen and should not be used unless there is no available alternative for organ-threatening disease in the mother, preferentially in the late second or third trimester. Fetal loss due to CYC toxicity may occur. MMF and MTX are listed as category D and X, respectively, and should be avoided. For biologic agents, data regarding safety during pregnancy are lacking and their use is generally discouraged. Pregnant SLE patients with a severe renal flare (active urinary sediment, increase in SCr) can be treated with high-dose GC and antihypertensives, *excluding* ACE inhibitors, whereas AZA can be used cautiously to allow steroid tapering. Prompt delivery of the fetus at the earliest safe time point possible is warranted.

Neonatal lupus occurs in some babies born by mothers with anti-SSA/Ro or anti-SSB/La antibodies, or both. The

most serious complication is neonatal complete heart block (CHB), which occurs in up to 2% of such pregnancies and carries a 20% to 30% mortality risk. The risk of recurrence in a mother having already borne a child with CHB ranges from 14% to 19%.¹⁷⁰ Therefore all women with SLE should be evaluated for the presence of anti-Ro/La antibodies. The most vulnerable period for the development of conduction disturbances is between week 18 and 26 of gestation, during which anti-Ro/La-positive patients should be evaluated with weekly fetal Doppler echocardiography for the prompt identification of conduction anomalies, mainly PR interval prolongation. If CHB develops, no modality has been shown to reverse it. In contrast, a large observational study in 118 pregnant women with anti-Ro antibodies showed that first-degree block may be reversed by fluorinated GCs such as dexamethazone (4 mg/day) initiated at the time of diagnosis and continued throughout pregnancy.¹⁷¹ Two trials found no beneficial effect of IVIG on prevention of recurrence of congenital heart block in Ro/SSA-positive mothers.^{172,173}

Regarding breastfeeding, the American Academy of Pediatrics (AAP) states that nursing is permissible for women receiving GC but the interval between dose and nursing should be at least 4 hours if the prednisone dosage is greater than 20 mg/day. Antimalarials may be continued during lactation, whereas AZA is not recommended due to possible risk for immunosuppression, carcinogenicity, and growth restriction of the child. MTX, MMF, CsA, leflunomide, and CYC are also contraindicated.

The high-risk features of SLE pregnancy and the possible risk for adverse outcomes highlight the importance of family counseling and planning before pregnancy is sought. It is generally accepted that pregnancy outcome is optimal when disease is clinically quiescent for at least 6 months and, in cases of kidney involvement, if renal function is normal or near normal. Until this desired goal is reached, common effective means of contraception should be taken to avoid unplanned pregnancies (see Women's Health Issues).

Table 81-7 Approach to the Management of Pregnancy in Systemic Lupus Erythematosus

Planning of pregnancy
Ensure that lupus is inactive for at least 6 mo
Reassure patient: small risk for major flare
Discourage pregnancy if SCr >2 mg/dL
Determine aPL antibodies and other antibodies that may be of relevance (anti-SSA, anti-SSB)
Obtain baseline serology and chemistry labs (SCr, SAlb, uric acid, anti-dsDNA, C3/C4)
Be aware of the small risk for CHB, especially in women with both anti-SSA and anti-SSB antibodies or with a prior episode of CHB. In such cases, may monitor for CHB between 16 and 24 wk of gestation
Monitor closely blood pressure and proteinuria. Should this develop, differentiate between active nephritis and pre-eclampsia
Presence of generalized lupus activity, active urine sediment, and low serum complement are in favor of lupus nephritis
For patients with antiphospholipid syndrome, consider combined heparin and aspirin to reduce risk for pregnancy loss and thrombosis. Patients with aPL antibodies may be treated with aspirin, although there are no adequate data to support its use

CHB, congenital heart block.

Treatment of Pediatric Systemic Lupus Erythematosus

Pediatric-onset SLE (pSLE) represents 15% to 20% of all SLE cases and is associated with higher disease severity and more rapid damage accrual than adult-onset SLE. The use of antimalarials (HCQ 4 to 6 mg/kg/day) is helpful in children with skin disease and arthritis. In mild nephritis (class II or mild class III LN), normal renal function, normal blood pressure, and non-nephrotic proteinuria, oral GCs (≤ 1 mg/kg/day) may suffice to control disease. Initial pulses of IV-MP (30 mg/kg/day up to a maximum dose of 1 g/day for 3 consecutive days) may allow for lower oral prednisone dose (0.5 mg/kg/day). In patients with class III nephritis and high activity index or class IV disease, pulse therapy with IV-MP and IV-CYC (0.75 to 1 g/m²) should be considered. Lehman and colleagues^{174,175} studied clinical and histologic progression of class III/IV nephritis in 16 children who completed at least 3 years of continuous treatment with IV-CYC. Significant improvements in disease activity, renal function, and renal activity index were observed. In a retrospective study of 28 patients with class IV LN who received IV-CYC and oral GC, repeat biopsy showed

histologic improvement in 20 out of 25 children. At last follow-up, 3.5 ± 2.3 years after second biopsy, 26 patients retained normal renal function.¹⁷⁶ In PLN with preserved renal function and non-nephrotic proteinuria, MMF could be used.¹⁷⁷ A single study has reported good outcomes with the combination of MMF and CsA in severe class III/IV LN patients who responded inadequately to initial induction therapy with MMF and GC.¹⁷⁸

Both AZA and MMF are efficacious maintenance regimens in pediatric PLN.^{179,180} Baskin and colleagues¹⁸¹ studied 20 pSLE patients with severe PLN who received 6-month induction therapy with pulse IV-MP (30 mg/kg, followed by oral prednisone 0.5 to 1.0 mg/kg/day) and IV-CYC (500 mg/m²). AZA (2 mg/kg/day) was commenced as a remission-maintaining regimen in all patients; in 10 patients, treatment subsequently switched to oral MMF (1200 mg/m²/day) because of intolerance or lack of efficacy. Following this approach, 14 patients (70%) achieved complete remission and another 3 (15%) had partial remission. An alternate-day regimen of 10 to 15 mg oral prednisone should be aimed at during the maintenance phase.

Renal flares remain an important issue that has not been adequately addressed. Alternative to a second course of IV-CYC and GC, which may be associated with significant long-term toxicity, is the combination of IV MTX and CYC administered for 9 months.¹⁷⁵ Although data for RTX are limited, it may be used (600 mg/m², maximum dose of 1 g/m² on days 1 and 15) in refractory renal and extrarenal disease.^{182,183} RTX can be used as monotherapy or in combination with CYC, under the following dosage scheme: 500 to 750 mg/m² on days 2 and 16.

Significant CNS involvement usually warrants combination of high-dose steroids with an immunosuppressive agent such as CYC or AZA.¹⁴⁷ To date, there is no study documenting an increased rate of serious adverse effects such as life-threatening infections or secondary neoplasia in children with SLE receiving cytotoxic therapy compared with adults. All children with LN should be regularly reviewed to treat accompanying hypertension, proteinuria, and renal dysfunction. Monitoring for normal growth, physical and pubertal development, and bone density is important, especially for patients on long-term treatment with GC.

COMORBIDITIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

KEY POINTS

The diagnostic approach and management of an SLE patient with possible infection should consider: (1) the dominant clinical syndrome, (2) the history of epidemiologic exposures, and (3) the “net-state” of immunosuppression.

Immunizations are safe and effective in SLE patients but must be avoided in active disease. Inactivated live vaccines are contraindicated in patients taking immunosuppressive drugs or high-dose glucocorticoids.

In SLE patients with end-stage renal disease, hemodialysis may be preferred over chronic ambulatory peritoneal dialysis. Renal transplantation is a potential alternative.

SLE patients are at increased risk for cardiovascular disease, and strict adherence to general population guidelines for primary prevention is recommended.

Cervical dysplasia is increased in women with lupus. HPV vaccination should be considered until the age of 25 years, similarly to the general population.

Infections and Immunizations

Risk Factors and General Management

Infections account for 20% to 55% of all deaths in SLE patients. Susceptibility to infections may be due to underlying immune dysregulation and therapeutic factors, particularly high-dose GCs and immunosuppressive drugs. A broad spectrum of infections have been reported in SLE including bacterial, mycobacterial, viral, fungal and parasitic infections, with the respiratory, urinary tract, and CNS as the most commonly involved sites.¹⁸⁴ Risk factors for infections include increased clinical or serologic lupus activity, or both, at baseline^{185,186}; major organ involvement (especially renal¹⁸⁷ and lung involvement¹⁸⁸); lymphopenia; persistent neutropenia ($<1000/\text{mm}^3$)¹⁸⁹; hypoalbuminemia (especially for severe CNS infections¹⁹⁰); high dose of GC (each increase of 10 mg/day prednisone is associated with 11-fold increased risk for serious infection¹⁸⁸); and prior (within the last 6 months) use of immunosuppressive drugs (especially AZA and CYC).^{186,191,192}

The evaluation of a lupus patient who receives immunosuppressive therapy and presents with symptoms or signs suggestive of infection possesses diagnostic and therapeutic challenges (Figure 81-3). This is complicated by the fact that active SLE per se is associated with increased risk for infection, and on the other hand, viral infections can mimic a lupus flare. Findings that favor the diagnosis of infection include the presence of shaking chills, leukocytosis and/or neutrophilia (especially in the absence of steroid therapy), increased numbers of band forms or metamyelocytes on peripheral blood smear, and concomitant immunosuppressive therapy.¹⁹²⁻¹⁹⁵ The diagnosis of SLE fever is favored by the presence of leukopenia (not explained by cytotoxic therapy), normal or only slightly increased C-reactive protein, low C3/C4, and elevated anti-DNA antibodies. If fever fails to resolve in a patient receiving prednisone 20 to 40 mg daily, it is likely that that fever is due to infection, not SLE. Elevated serum procalcitonin (PCT) levels have been reported to be predictive of bacterial or mycotic infections,¹⁹⁶ although their diagnostic utility in patients with systemic autoimmune diseases has been questioned.¹⁹⁷ Pending microbiology results, adequate antimicrobial therapy (including broad-spectrum antibiotics in suspected nosocomial infection) is recommended to reduce adverse outcomes.^{198,199}

Specific and Opportunistic Infections

Tuberculosis Infection. Tuberculosis (TB) infection rates are 6- to 60-fold higher in SLE patients than the general population²⁰⁰ and may be caused by both *Mycobacterium tuberculosis* (MTB) and nontuberculous mycobacterium (NTM).²⁰¹ Extrapulmonary involvement is

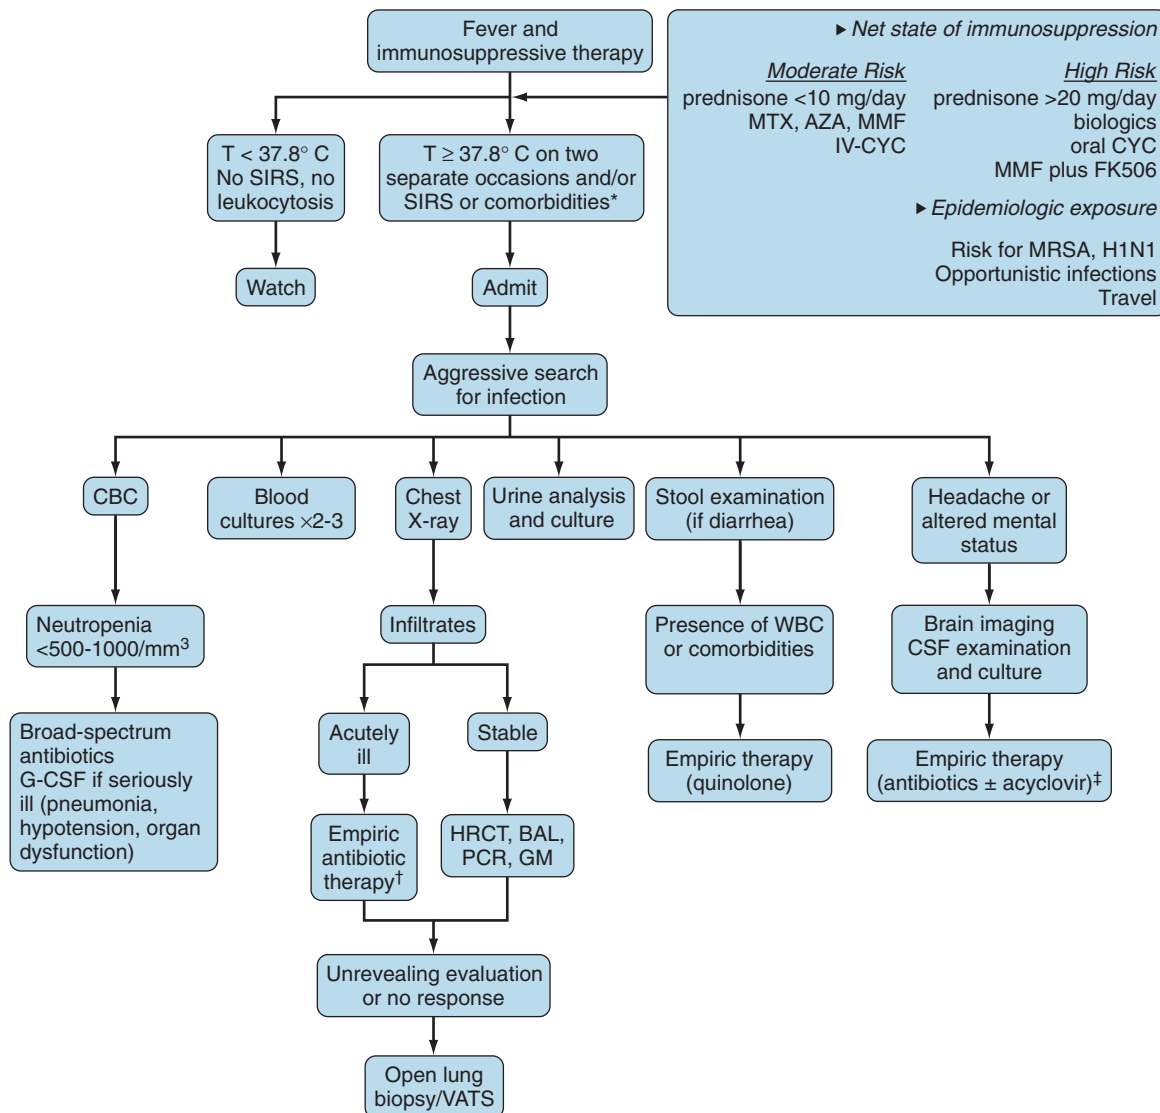

Figure 81-3 Initial assessment and management of systemic lupus erythematosus patients who receive immunosuppressive therapy and present with fever or other symptoms and signs suggestive of infection. *, Systemic inflammatory response syndrome (SIRS): $T \geq 38^\circ\text{C}$ or $<36^\circ\text{C}$, tachycardia (heart rate $>90/\text{min}$), tachypnea (respiratory rate $>20/\text{min}$), white blood cells (WBC) $>12,000/\text{mm}^3$; comorbidities: age older than 65 years, diabetes, chronic cardiopulmonary disease. †, Consider empirical therapy for *Pneumocystis pneumonia* in severe hypoxemia or diffuse pulmonary infiltrates. ‡, Consider tuberculosis and other opportunistic central nervous system (CNS) infections. AZA, azathioprine; BAL, bronchoalveolar lavage; CBC, complete blood count; CSF, cerebrospinal fluid; G-CSF, granulocyte colony-stimulating factor; GM, galactomannan; H1N1, influenza H1N1; HRCT, high-resolution chest tomography; IV-CYC, intravenous cyclophosphamide; MMF, mycophenolate mofetil; MRSA, methicillin-resistant *Staphylococcus aureus*; MTX, methotrexate; PCR, polymerase chain reaction; T, temperature; VATS, video-assisted thoracoscopy. (Modified from Papadimitrakaki ED, Bertisias K, Chamilos MD, Boumpas DT: Systemic lupus erythematosus: cytotoxic drugs. In Tsokos G, Buyon JP, Koike T, Lahita RG, editors: Systemic lupus erythematosus, ed 5, St Louis, 2010, Elsevier, pp 1083–1108.)

common and ranges from 52% to 74% of TB infections. Tuberculin skin testing (TST) is recommended for patients who are candidates for treatment with long-term prednisone greater than or equal to 15 mg/day or immunosuppressive drugs. Because of the isoniazid age-related hepatotoxicity (4.6% in individuals older than 65 years of age vs. 0.3% in 20- to 30-year-old individuals), TST is advocated only for moderate-risk patients younger than 65 years of age. TB diagnosis can be established by conventional methods including the presence of a suggestive clinical presentation, a positive TST, and microbiologic confirmation (by the identification of bacilli in the smear or positive cultures). In selected patients, when these measures are

nondiagnostic, typical histologic abnormalities such as granulomas may help in the diagnosis. The advent of the T cell IFN- γ release assays, a more specific test than the tuberculin skin test, may improve the detection of latent TB infection.

***Pneumocystis jiroveci* Infection.** The incidence of *Pneumocystis pneumonia* in SLE patients on CYC approximates 0.15%. Risk factors include lymphopenia ($\leq 750/\text{mm}^3$) during lupus treatment, high disease activity, renal involvement, interstitial pulmonary fibrosis, and high prednisone dosage.²⁰² Some authors recommend *Pneumocystis pneumonia* prophylaxis (one double-strength tablet of trimethoprim-sulfamethoxazole three times a week or

dapsone 100 mg/day if allergic to sulfamethoxazole) for patients on high-dose GC (≥ 20 mg/day prednisone or equivalent) alone or in combination with cytotoxic drugs, especially if CD4 count is less than 300 cells/mm³. Of note, risk of allergic reactions to sulfamethoxazole may be increased in SLE patients.

Viral Infections. The most commonly reported viral infections in SLE patients are parvovirus B19 and cytomegalovirus (CMV) (predominantly in severely immunosuppressed patients). The latter may mimic a lupus flare or present with specific organ involvement such as hepatitis, gastrointestinal bleeding, or pulmonary infiltrates. Renal insufficiency, lymphopenia, APS manifestations, treatment with CYC, multiorgan involvement at presentation, and a lower frequency of antiviral treatment have been related to fatal viral infection in SLE cohorts.^{203,204} The introduction of direct antigenic (CMV pp65 antigenemia) and molecular (quantitative polymerase chain reaction [PCR]) testing has revolutionized the diagnosis of CMV infection in the setting of immune suppression. Viral load has proven useful for diagnosis of infection, prediction of disease, and monitoring response to therapy. However, detection of small amounts of viral DNA in peripheral blood by PCR is not necessarily indicative of clinically significant CMV infection, and correct interpretation of test results may require consultation with an infectious diseases specialist. Further confirmatory diagnosis of organ-specific involvement can be made by histologic detection of characteristic inclusion bodies. Increased age (≥ 60 years), symptomatic infection, and lymphopenia (all three correlating with CMV antigenemia above 5.6/10⁵ PMNs) have been associated with fatal outcome, and their presence may therefore prompt initiation of antiviral therapy.²⁰⁴

Varicella-zoster virus (VZV) reactivation is an important issue in SLE patients. Risk factors include history of CYC or AZA exposure, the presence of concurrent or previous malignancy, and LN. Shingles dissemination and bacterial superinfection are mostly linked to high-dose GC treatment.²⁰⁵ SLE patients do not display increased risk for HIV infection, and screening should be based on individualized risk factors. Due to risks of occurrence and reactivation of the infection following immunosuppressive therapy, particularly when steroids are administered, screening for hepatitis C and B virus is prudent before starting such therapies.

Immunizations

Although vaccination may hypothetically induce polyclonal cell activation in lupus precipitating a flare, it is felt to be safe.²⁰⁶ Vaccines, however, should not be given to patients with active disease. Inactivated live vaccines (measles, mumps, rubella, polio, VZV, and vaccinia [smallpox]) are contraindicated in patients taking immunosuppressive drugs or prednisone, or both, at a dose greater than 20 mg/day. Influenza vaccine is safe and effective, although seroprotection and seroconversion rates are lower than those in healthy controls^{207,208}; booster vaccination does not increase antibody titers in annually vaccinated patients.²⁰⁹ Pneumococcal vaccine is also safe, but the resultant antibody titers may be decreased in SLE patients; use of GC may contribute to blunted antibody responses. Protective immune response can be achieved safely in SLE patients

with both tetanus toxoid and *H. influenzae* type B in addition to pneumococcus.

According to the Advisory Committee on Immunization Practices (ACIP) guidelines and EULAR guidelines,²¹⁰ individuals older than 60 years of age should be vaccinated with a single dose of VZV vaccine. This is a live-attenuated vaccine and should be administered at least 14 days before initiation, or it should be deferred for at least 1 month after discontinuation of high-dose GC or immunosuppressive therapy. Therapy with low-dose MTX (<0.4 mg/kg/week) or AZA (<3 mg/kg/day) is not considered sufficiently immunosuppressive to create vaccine safety concerns. Kuruma and colleagues²¹¹ reported on hepatitis B vaccination in inactive SLE patients treated with low-dose GC and not receiving immunosuppressive drugs, negative for anti-dsDNA and aCL antibodies. Patients were administered a recombinant vaccine. All patients developed protective antibodies, and there were no SLE flares.

Chronic Kidney Disease and End-Stage Renal Disease

Risk Factors and Dialysis

Approximately 10% to 20% of SLE patients will develop ESRD. Clinical predictors are abnormal SCr values at presentation, delay in treatment initiation, failure to achieve remission, and systolic hypertension.²¹²⁻²¹⁵ Progression of LN to the point of dialysis does not necessarily indicate ESRD because 5% to 10% of patients will recover sufficient renal function to interrupt dialysis at least temporarily. Patients with rapid deterioration of renal function are more likely to have a reversible physiologic (dehydration, infection, acute tubular necrosis) or pathologic (crescentic glomerulonephritis) component accounting for their renal insufficiency. In these patients, immunosuppressive therapy (pulse of IV-MP and IV-CYC 0.4 to 0.5 g/m², administered 8 to 10 hours before dialysis) may continue during dialysis.

The 5-year survival rate of SLE patients on dialysis approximates 80% to 90%, comparable with that in non-SLE dialysis patients.²¹⁶ Hemodialysis may be the first choice of renal replacement therapy, especially for patients who are still on immunosuppressive therapy, due to increased rates of infectious complications (most commonly peritonitis) and hospital admissions in patients on chronic ambulatory peritoneal dialysis (CAPD).^{216,217} Irrespective of the dialysis mode, most patients with advanced renal disease experience a decline in lupus activity. Discontinuation of cytotoxic therapy may be considered in patients with steadily rising SCr to greater than or equal to 5 mg/dL with inactive urine sediment, renal biopsy showing exclusively scarring and atrophy, or contracted renal size. Judicious use of GCs and immunosuppressive drugs is essential to minimize the risk for septic complications. Cardiovascular morbidity and mortality are also increased in patients with ESRD, underscoring the need for tight control of atherosclerotic risk factors.²¹⁸

Renal Transplantation

Renal transplantation is a viable alternative for lupus patients with ESRD. Graft and patient survival rates are

comparable with those in other patient groups, although this is not confirmed in all studies.²¹⁶ Results are superior with living than cadaveric donor transplantation (5-year graft survival rates 77% to 89% vs. 41% to 58%). If a living donor is available, the possibility for pre-emptive transplantation can be considered because this approach is associated with superior graft and patient outcomes in other kidney diseases.²¹⁹ Nevertheless, a period of at least 3 months on dialysis may allow some patients to recover adequate renal function for significant time periods.

There are no prospective studies comparing various immunosuppressive regimens after renal transplantation in SLE. Calcineurin inhibitors should generally be included in the induction phase (6 to 12 months) on the basis of observations of improved graft survival rates since their introduction in lupus transplantation.²²⁰ Due to potential nephrotoxicity and adverse effects on cardiovascular disease (CVD) risk factors, their use should be minimized during the maintenance phase and other immunosuppressive agents (MMF, AZA) should be preferentially employed. Recurrence of LN (usually mild mesangial proliferative disease) in the renal allograft is a rare event (2% to 3%) and not an important cause of graft loss. Risk factors for recurrent LN include non-Hispanic black race, female gender, age younger than 33 years, and living donor transplantation.²²¹⁻²²³ APS has been associated with post-transplant renal thrombosis and poor graft outcome and warrants anticoagulation therapy.²²⁴

Cardiovascular Morbidity

SLE patients have a 2.3 to 7.5 increased risk for developing coronary heart disease compared with age-matched controls, after adjusting for traditional CVD risk factors.²²⁵ In lupus, traditional CVD risk factors are reinforced by disease-related risk factors such as circulating prothrombotic aPL antibodies, antibodies against high-density lipoprotein cholesterol (HDL-C) interfering with its function, a typical lupus-pattern of dyslipidemia (low HDL-C, high triglycerides, normal or slightly elevated low-density lipoprotein cholesterol (LDL-C), and abnormal serum homocysteine levels), and the proatherogenic effect of systemic inflammation.²²⁶

Tight control of CVD risk factors is recommended for SLE patients, according to risk stratification and the presence of comorbidities. Hypertension requires diligent monitoring and treatment because it has been associated with worse outcomes in LN. For patients with nephritis and proteinuria greater than 1 g/day, target blood pressure should be less than 110/70 mm Hg. For most cases, ACE inhibitors or angiotensin receptor blockers (ARBs), or both, are the initial treatments of choice. For dyslipidemia, Wajed and colleagues²²⁷ advocated for the institution of dietary or lipid-lowering therapy toward a target LDL-C less than 101 mg/dL in all SLE patients without stratifying for presence of other risk factors. Similarly, many clinicians follow the National Cholesterol Education Program Adult Treatment Panel III guidelines for the use of statins in primary CVD prevention, considering SLE as a coronary heart disease risk factor equivalent to diabetes. However, this approach is not universally accepted because it may lead to overtreatment of LDL-C levels.²²⁸ Nonetheless, aggressive

treatment of dyslipidemia (target LDL-C <100 mg/dL and triglycerides <150 mg/dL) is recommended for patients with multiple risk factors, especially those with moderate or severe lupus. Although CVD is the leading cause of death among women and it carries a higher mortality than men (44% vs. 27%), a large survey revealed that only 13% of the women recognized the magnitude of the problem.²²⁹ This, coupled with the greater challenge the diagnosis of coronary disease poses in women compared with men owing to its often atypical presentation, emphasizes the importance of sensitization of lupus women regarding their increased probability to develop CVD.²³⁰

Osteoporosis

Ongoing disease activity, premature menopause caused by use of immunosuppressive drugs, relative vitamin D deficiency due to avoidance of sun exposure, and the use of systematic GCs all contribute to reduced bone mineral density (BMD) in SLE patients.²³¹ Vertebral compression fractures are common, especially as the age of patients increases.²³² Quality indicators regarding osteoporosis prevention and therapy suggest that (1) all SLE patients receiving prednisone greater than or equal to 7.5 mg/day for 3 or more months should undergo BMD testing unless already on antiresorptive or anabolic therapy and receive osteoporosis prophylaxis with calcium and vitamin D supplements and (2) patients receiving prednisone greater than or equal to 7.5 mg/day for 1 or more months and having a central T score of -2.5 or less or a history of fragility fracture should be treated with an antiresorptive or anabolic agent unless contraindications exist.²³³ This daily prednisone dosage is higher than the guideline proposed by the ACR for prevention of steroid-induced osteoporosis (5 mg/day) in the general patient population. The authors recommend osteoporosis prophylaxis with daily prednisone doses of greater than or equal to 5 mg for postmenopausal women and greater than or equal to 7.5 mg for premenopausal women.

Malignancy in Lupus

Hematologic malignancies (particularly non-Hodgkin's lymphoma [NHL]) and cervical and lung cancer occur more commonly in SLE compared with the general population, followed by rare forms of malignancy affecting the hepatobiliary tract and the vulva/vagina. Immunosuppressive therapy (with the potential for mutagenesis and the impairment of antitumor immune surveillance) and intrinsic SLE-related mechanisms (chronic antigenic stimulation, impaired surveillance) may account for this risk.

NHL is associated with SLE (standardized incidence ratio [SIR], 3.6),^{234,235} with the most commonly identified histologic subtype being diffuse large B cell lymphoma, which usually runs an aggressive course. Hodgkin's lymphoma (HL) is also more frequent in SLE (SIR, 3.2).²³⁶ The risk for hematologic malignancies may increase after exposure to immunosuppressive medications, particularly after a period of 5 years following cessation of therapy. Because SLE and lymphomas share clinical manifestations (fever, lymphadenopathy, splenomegaly, cytopenias, and monoclonal expansion of B cells), a high index of suspicion is necessary for early detection of the latter. In such cases, an aggressive

investigation is warranted with appropriate imaging studies and potentially lymph node biopsy.

Cervical dysplasia is increased in women with lupus^{237,238} as a result of impaired clearance of human papillomavirus (HPV) due to exposure to immunosuppressive agents, particularly CYC (increase by 1 g of IV-CYC exposure corresponding to 13% increased risk of cervical intraepithelial neoplasia [CIN]). Therefore SLE should be regarded as a risk factor for cervical malignancy and high-risk HPV infection. The authors would recommend cervical cytology for cancer screening once (EULAR) or twice (U.S. Preventive Services Task Force) in the first year and then annually, adding HPV testing to the first-year-obtained cervical smears and then modifying subsequent screening on the basis of these results (cervical cytology screening every 6 months for women with detectable HPV DNA and annually for others). Although the efficacy of HPV vaccine has not been investigated in patients with autoimmune diseases, EULAR guidelines concluded that HPV vaccination should be considered for women with SLE until the age of 25 years, similar to the general population.²¹⁰

SLE patients have a moderately increased risk for lung cancer (SIR, 1.4), mostly adenocarcinomas,²³⁵ yet this risk is higher in SLE patients who smoke.²³⁹ While waiting for the final verdict on the use of chest computed tomography as a screening test in the smoking population, smoking and nonsmoking patients should be evaluated similarly to the general population. With regard to breast cancer, there is no evidence for increased risk in SLE and thus no particular recommendation should be applied beyond screening guidelines used in the general population.

Emergencies in Patients with Lupus

SLE patients may visit the emergency department (ED) for complications related to lupus itself, lupus treatment, or unrelated reasons. Critical questions confronting the clinician are (1) whether the event is related to lupus and (2) whether in the presence of lupus the management should differ. In general, lupus-related emergencies frequently occur when disease is active. For example, approximately 60% of primary NPSLE events occur in the presence of generalized lupus activity. Common symptoms bringing lupus patients to the ED are fever, shortness of breath, and chest pain. Poor compliance, low education level, severity of the underlying disease, and higher damage scores are risk factors for hospitalization.

SLE patients might also develop life-threatening organ dysfunction, related to disease activity or immunosuppressive therapy, severe enough to require admission to the intensive care unit (ICU). Infections are the leading cause of admission (45% to 61%). Hsu and colleagues²⁴⁰ studied 51 SLE patients admitted to the ICU and identified intracranial hemorrhage, gastrointestinal hemorrhage, and septic shock as poor outcome predictors. High APACHE II scores and use of vasopressors have been associated with patient mortality.²⁴¹ Overall mortality in SLE patients admitted to the ICU is high, although it has declined during the past decade (from 47% to 24%).^{241,242} An aggressive search for infection together with recommended empiric antimicrobial therapy is crucial. When it is not clear whether the underlying process is related to infection or active disease,

empiric antimicrobial therapy together with high-dose GC (0.5 to 1 mg/kg/day) may suffice. Once infection has been ruled out, pulse steroids or CYC, or both, may be used. Agents such as IVIG, plasmapheresis, and RTX may be considered as adjuvant therapy in life-threatening disease or in cases of deterioration or inadequate response following 1 to 2 weeks of therapy.

WOMEN'S HEALTH ISSUES

KEY POINTS

Synthetic gonadotropin releasing hormone analogues significantly decreased rates of gonadal failure in young women with severe SLE treated with CYC.

Contraceptive methods including hormone agents are generally safe for most SLE patients.

Premature ovarian failure is an age- and dose-dependent adverse effect of CYC therapy, whereas male gonadal toxicity may be observed with as little as 7 g cumulative CYC dose. Strategies to preserve fertility in postpubertal SLE women include hormonal contraceptives, gonadotropin releasing hormone (GnRH) antagonists, and embryo and oocyte cryopreservation. Ovarian tissue banking for future tissue transplantation has been suggested for prepubertal girls. Individual patient preferences should be considered when deciding about fertility preservation. Some authors have suggested that coadministration of GnRH antagonists confers protection against premature ovarian failure and therefore recommend a GnRH antagonist-based protocol in CYC-treated female patients. In men receiving CYC for malignancies, frequency of azoospermia ranges from 30% to 90%. Administration of testosterone and sperm banking represent valid strategies for preservation of testicular function and fertility (see [Table 81-4](#)).²⁴³

Contraceptive methods are generally safe for most SLE patients. Previous research had suggested that hormonal agents might increase the risk of disease flares. However, two RCTs found no increase in flares in those without severe disease activity at study entry, and a systematic review concluded that benefits of use outweigh potential risks for most contraceptive methods.²⁴⁴ However, women with positive aPL antibodies should avoid combined hormonal methods because of an increased risk for thrombosis. Coexisting conditions such as severe thrombocytopenia, atherosclerosis, hypertension, and venous thrombosis could also make certain contraceptives less advisable.

Women with SLE may experience lower urinary tract symptoms, often accompanied by voiding dysfunction (small bladder capacity, low urinary flow rate).²⁴⁵ Urinary bladder involvement is thought to contribute to recurrent urinary tract infections in some SLE patients.²⁴⁶ The approach to investigation and management of recurrent urinary tract infections is similar to that in the general population; control of disease activity may prevent bladder dysfunction. Lupus mastitis represents a rare form of lupus panniculitis occurring in 2% of women with SLE and may clinically mimic breast carcinoma.²⁴⁷ GC treatment is

generally effective, but refractory forms may necessitate surgical excision.

EVIDENCE AND EXPERT-BASED RECOMMENDATIONS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Due to the systemic nature of SLE, multiple medical subspecialties are involved in the care of these patients, dictating an integrated approach to their care. To this end, EULAR has developed recommendations covering the most important aspects in the diagnosis, management, and monitoring.^{125,133,210,248} These recommendations—developed not only for the specialists but for all internists and primary care physicians—are based on a combined research-based evidence approach and expert opinion consensus.

Future Directions

This past decade has witnessed major advances in defining risk factors and phenotypes, elucidating pathogenesis, and optimizing treatment. Recognition of adjuvant-like factors that promote the production of type I interferon via Toll-like receptors offers new targets for therapy in addition to those targeting B and T cells. Exploration of the genetic and environmental factors that determine susceptibility to disease may eventually lead to the identification of individuals at risk and elucidate the primary events that cause autoimmunity. In contrast to monogenic diseases, the expansion of personalized medicine in lupus awaits a more complete description of predisposition. Genome-wide, next-generation sequencing efforts now under way will provide within the next few years a more comprehensive description of the relations between genome sequence variation and clinical phenotypes.

Meanwhile, new drugs have been added to the armamentarium against the disease and new therapeutic strategies are aimed at inducing prompt remission with more intense therapy and prevention of flares with less toxic therapies. The introduction of MMF has added a useful new drug while providing additional valuable insights in trial design in lupus. Despite past efforts devoted to arguing on the choice of specific agents, there is finally a consensus that what is more important is a strategy aiming at remission and its maintenance with the treatment that best fits the patient. With the approval of the first biologic agent in March 2011, the disease is finally showing signs of yielding to more targeted therapy and unraveling its heterogeneity and complexity. Most importantly, it has become clearer than ever that optimal long-term outcome requires not only treatment of the disease flares but also management of its comorbidities. To this end, lupus highlights the need for a multidisciplinary approach and superb internal medicine skills.

Antiphospholipid Syndrome

DORUK ERKAN • JANE E. SALMON •
MICHAEL D. LOCKSHIN

KEY POINTS

Antiphospholipid antibodies (aPLs) are a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2 -glycoprotein I.

The clinical manifestations range from asymptomatic to catastrophic antiphospholipid syndrome (APS).

Stroke is the most common presentation of arterial thrombosis; deep vein thrombosis is the most common venous manifestation.

Pregnancy losses typically occur after 10 weeks' gestation (fetal loss), but earlier losses also occur.

Catastrophic APS is a rare form of APS that consists of multiple thromboses of medium and small arteries occurring over days.

Diagnosis should be made in the presence of characteristic clinical manifestations and persistently positive aPLs (measured at least 12 weeks apart).

Prevention of secondary thrombosis lacks a risk-stratified approach; the effectiveness of high-intensity anticoagulation in APS patients with vascular events is not supported by prospective controlled studies.

A common strategy to prevent fetal loss in aPL-positive patients with a history of pregnancy morbidities is low-dose aspirin and heparin.

Primary thrombosis prevention in persistently aPL-positive individuals requires a risk-stratified approach; elimination of reversible thrombosis risk factors and prophylaxis during high-risk periods are crucial. The effectiveness of aspirin in persistently aPL-positive patients without vascular events is not supported by prospective controlled studies.

Currently, no evidence indicates that anticoagulation is effective for nonthrombotic manifestations of aPLs, such as thrombocytopenia or heart valve disease.

Catastrophic APS patients usually receive a combination of anticoagulation, corticosteroids, intravenous immunoglobulin (IVIG), and plasma exchange.

Diagnosis of the antiphospholipid syndrome (APS) requires that a patient have both a clinical event (thrombosis or pregnancy morbidity) and the persistent presence of antiphospholipid antibody (aPL), documented by a solid phase serum assay (anticardiolipin or anti- β_2 -glycoprotein I [anti- β_2 GPI] immunoglobulin [Ig]G or IgM), a coagulation assay (inhibitor of phospholipid-dependent clotting—the lupus anticoagulant test), or both. Preliminary (Sapporo) classification criteria for APS,¹ revised in 2004,² are listed in Table 82-1.

Certain factors are not included as criteria but may be helpful in the diagnosis of individual patients. These include IgA anticardiolipin or anti- β_2 GPI, valvular heart disease, thrombocytopenia, early preeclampsia, and livedo reticularis (Table 82-2). These factors are rare, nonstandardized, or nonspecific phenomena that are too unreliable for use in clinical studies, but they occur in a sufficient number of patients to support a suspected diagnosis.

APS can occur as an isolated diagnosis, or it can be associated with systemic lupus erythematosus (SLE) or another rheumatic disease. Transient aPL, but probably not the syndrome, can be induced by drugs and infection.³

EPIDEMIOLOGY

Low-titer, usually transient, anticardiolipin occurs in up to 10% of normal blood donors,^{4,5} and moderate- to high-titer anticardiolipin or a positive lupus anticoagulant test occurs in less than 1%. The prevalence of positive aPL tests increases with age. Ten percent to 40% of SLE patients⁵ and approximately 20% of rheumatoid arthritis patients⁶ have positive aPL tests.

Based on a limited number of uncontrolled and non-risk-stratified studies, asymptomatic (no history of vascular or pregnancy events) aPL-positive patients have a 0% to 4% annual risk of thrombosis; patients with other autoimmune diseases such as SLE are at the higher end of the range.^{7,8} The aPL profile (low vs. high risk for thrombosis) and patients' clinical characteristics (presence or absence of other acquired or genetic thrombosis risk factors) influence the individual risk of thrombosis.⁹ Ten percent of first-stroke victims have aPLs,¹⁰ especially those who are young (up to 29%),^{5,11} as do up to 20% of women who have suffered three or more consecutive fetal losses.¹² Fourteen percent of patients with recurrent venous thromboembolic disease have aPLs.¹³

CAUSE

The main antigen to which aPLs bind is not a phospholipid but rather a phospholipid-binding plasma protein, namely, β_2 GPI (apolipoprotein H). β_2 GPI is normally present in serum at a concentration of 200 mg/mL, is a member of the complement control protein family, and has five repeating domains and several alleles. An octapeptide in the fifth domain and critical cysteine bonds are necessary for both phospholipid binding and antigenicity¹⁴; a first-domain site activates platelets.^{15,16} In vivo, β_2 GPI binds to phosphatidylserine on activated or apoptotic cell membranes, including those of trophoblasts, platelets, and endothelial cells. Under physiologic conditions, β_2 GPI may function

Table 82-1 Revised Sapporo Classification Criteria for Antiphospholipid Syndrome

Clinical Criteria	
1. Vascular thrombosis*	One or more clinical episodes [†] of arterial, venous, or small vessel thrombosis [‡] in any tissue or organ
2. Pregnancy morbidity	(a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th wk of gestation, or (b) One or more premature births of a morphologically normal neonate before the 34th wk of gestation because of eclampsia, severe preeclampsia, or recognized features of placental insufficiency [§] , or (c) Three or more unexplained consecutive spontaneous abortions before the 10th wk of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded
Laboratory Criteria	
1.	Lupus anticoagulant present in plasma on two or more occasions at least 12 wk apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis
2.	Anticardiolipin antibody of immunoglobulin (Ig)G or IgM isotype in serum or plasma, present in medium or high titer (>40 GPL or MPL, or >99th percentile), on two or more occasions at least 12 wk apart, measured by a standardized ELISA
3.	Anti- β_2 -glycoprotein I antibody of IgG or IgM isotype in serum or plasma (in titer >99th percentile) present on two or more occasions at least 12 wk apart, measured by a standardized ELISA
Definite APS is present if at least one of the clinical criteria and one of the laboratory criteria are met. Classification of APS should be avoided if less than 12 wk or more than 5 yr separate the positive antiphospholipid antibody test and the clinical manifestation. In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.	

*Coexisting inherited or acquired factors for thrombosis are not reasons to exclude patients from APS trials. However, two subgroups of APS patients should be recognized by the presence and absence of additional risk factors for thrombosis. Indicative (but not exhaustive) cases include age (>55 yr in men and >65 yr in women), the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated low-density lipoprotein or low high-density lipoprotein cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index >30 kg/m², microalbuminuria, estimated glomerular filtration rate <60 mL/min), inherited thrombophilias, oral contraceptive use, nephritic syndrome, malignancy, immobilization, and surgery. Thus, patients who fulfill these criteria should be stratified according to contributing causes of thrombosis.

[†]A thrombotic episode in the past can be considered a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means, and that no alternative diagnosis or cause of thrombosis is found.

[‡]Superficial venous thrombosis is not included in the clinical criteria.

[§]Generally accepted features of placental insufficiency include an abnormal or nonreassuring fetal surveillance test (e.g., nonreactive nonstress test) suggestive of fetal hypoxemia, an abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia (e.g., absent end-diastolic flow in the umbilical artery), oligohydramnios (e.g., amniotic fluid index ≤ 5 cm), or a postnatal birth weight less than the 10th percentile for gestational age.

Investigators are strongly advised to classify APS patients participating in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, only lupus anticoagulant present; IIb, only anticardiolipin antibody present; IIc, only anti- β_2 -glycoprotein I antibody present. APS, antiphospholipid syndrome; ELISA, enzyme-linked immunosorbent assay.

From Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome, *J Thromb Haemost* 4:295–306, 2006.

in the elimination of apoptotic cells¹⁷ and as a natural anticoagulant.¹⁸

Other, less relevant antigens targeted by aPLs are prothrombin, annexin V, protein C, protein S, high- and low-molecular-weight kininogens, tissue plasminogen activator, factor VII, factor XI, factor XII, complement component C4, and complement factor H.¹⁹

In experimental animal models, passive or active immunization with viral peptides,²⁰ bacterial peptides,²¹ and heterologous β_2 GPI²² induces polyclonal aPLs and clinical events associated with APS. These data suggest that pathologic autoimmune aPL is induced in susceptible humans by infection via molecular mimicry.

However, infection-induced aPLs (syphilitic and non-syphilitic *Treponema*, *Borrelia burgdorferi*, human immunodeficiency virus, *Leptospira*, or parasites) are usually β_2 GPI independent and bind phospholipids directly.²³ Drugs (chlorpromazine, procainamide, quinidine, and phenytoin) and malignancies (lymphoproliferative disorders) can also induce β_2 GPI-independent aPLs. Conversely, autoimmune aPLs bind β_2 GPI or other phospholipid-binding plasma proteins, which in turn bind negatively charged phospholipids such as cardiolipin (β_2 GPI-dependent aPLs).

Low levels of aPLs may be present normally; one of the functions of normal aPLs may be to participate in the physiologic removal of oxidized lipids.

Table 82-2 Other Features Suggesting the Presence of Antiphospholipid Antibodies

Clinical
Livedo reticularis
Thrombocytopenia (usually 50,000-100,000 platelets/mm ³)
Autoimmune hemolytic anemia
Cardiac valve disease (vegetations or thickening)
Multiple sclerosis-like syndrome, chorea, or other myelopathy
Laboratory
IgA anticardiolipin antibody
IgA anti- β_2 -glycoprotein I

PATHOGENESIS

Antiphospholipid antibody is most likely related to thrombosis through multiple mechanisms; a proposed pathogenesis is illustrated in Figure 82-1. The process begins with activation or apoptosis of platelets, endothelial cells, or trophoblasts, during which phosphatidylserine (a negatively charged phospholipid) migrates from the inner to the normally electrically neutral outer cell membrane. Circulating β_2 GPI binds to phosphatidylserine, and then aPL binds to a β_2 GPI dimer.²⁴

Figure 82-1 Proposed mechanism of antiphospholipid antibody (aPL)-related thrombosis and placental injury. The negatively charged phospholipid phosphatidylserine (PS, yellow circles) migrates from the inner to the outer cell membrane during activation or apoptosis of platelets and endothelial cells, and it is normally present on trophoblasts. The neutral phospholipid phosphatidylcholine (PC, red circles) is the major constituent of the outer layer of unactivated cells. Dimeric β_2 -glycoprotein I (β_2 -GPI) then binds to PS (probably via β_2 -GPI surface receptors such as apoER2, annexin A2, or a Toll-like receptor), and aPL binds to β_2 -GPI, activating the classic complement pathway and leading to the generation of C5a, which induces (1) expression of adhesion molecules (e.g., intracellular adhesion molecule-1) and tissue factor (TF), and (2) activation of monocytes, polymorphonuclear (PMN) cells, and platelets, resulting in the release of proinflammatory mediators (e.g., tumor necrosis factor [TNF], vascular endothelial growth factor receptor-1) and initiation of the prothrombotic stage. Both nuclear factor κ B (NF κ B) and p38 mitogen-activated protein kinase (p38 MAPK) may play a role in the intracellular signaling cascade. Antiphospholipid antibodies also downregulate the expression of trophoblast signal transducer and activator of transcription 5 (STAT5), reducing the endometrial stromal cell production of prolactin (PRL) and insulin growth factor binding protein-1 (IGFBP-1).

Antiphospholipid antibody- β_2 -GPI dimer binding activates the complement cascade extracellularly; initiates an intracellular signaling cascade, probably through the C5a and β_2 -GPI surface receptors; and recruits and activates inflammatory effector cells, including monocytes, neutrophils, and platelets, leading to the release of proinflammatory products (e.g., tumor necrosis factor [TNF], oxidants, proteases) and the induction of a prothrombotic phenotype.²⁵⁻²⁷ The putative receptor of β_2 -GPI binding protein that transduces signals from the cell membrane to the nucleus is not yet identified and may vary among cells. The following candidates have been suggested: apoER2 (a member of the low-density lipoprotein receptor superfamily), annexin A2, and a Toll-like receptor.²⁸⁻³⁰ Both nuclear factor κ B and p38 mitogen-activated protein kinase may play a role in the intracellular signaling cascade.^{31,32}

In addition, through downregulation of the signal transducer and activator of transcription 5 (STAT5), aPLs inhibit the production of placental prolactin and insulin growth factor-binding protein-1,³³ and they adversely affect the formation of a trophoblast syncytium, placental apoptosis,

and trophoblast invasion—all processes that are required for the normal establishment of placental function.

Other possible contributory mechanisms of aPL-mediated thrombosis include inhibition of coagulation cascade reactions catalyzed by phospholipids (e.g., activation of circulating procoagulant proteins, inhibition of protein C and S activation), induction of tissue factor (a physiologic initiator of coagulation) expression on monocytes, reduction of fibrinolysis, and interaction with the annexin V anticoagulant shield in the placenta.²⁹

In experimental animal models, aPLs cause fetal resorption and increase the size and duration of trauma-induced venous and arterial thrombi.^{34,35} Inhibiting complement activation prevents experimental aPL-induced fetal death and angiogenic dysregulation—associated abnormal placental development and preeclampsia; C5 knockout mice carry pregnancies normally despite aPL,³⁶ implying that a complement-mediated effector mechanism is an absolute requirement for fetal death to occur. Complement activation is also required for experimental thrombosis.^{37,38} In addition, aPL-induced reduction of heparin-binding

epidermal growth factor–like growth factor leads to defective placentation.³⁹

Because high-level aPLs may persist for years in asymptomatic persons, it is likely that vascular injury, endothelial cell activation, or both immediately precede the occurrence of thrombosis in those bearing the antibody (second-hit hypothesis). Of note, at least 50% of APS patients with vascular factors possess other acquired thrombosis risk factors at the time of their events.^{40,41}

Persons congenitally lacking β_2 GPI⁴² and β_2 GPI knockout mice appear normal.⁴³ β_2 GPI polymorphisms influence the generation of aPLs in individuals, but they have only a weak relationship to the occurrence of APS.⁴⁴ A cluster of 50 upregulated genes may have an effect on the occurrence of thrombosis in aPL-positive individuals.⁴⁵

CLINICAL FEATURES

Clinical manifestations range from asymptomatic aPL positivity (no history of vascular or pregnancy events) to catastrophic APS (multiple thromboses occurring over days). Thus patients should not be evaluated and managed as if they have a single disease.

Vascular Occlusion

APS affects all organ systems. Its principal manifestations are venous or arterial thromboses and pregnancy loss (see Table 82-1). Except for their severity, the youth of affected patients, and the unusual anatomic locations (Budd-Chiari syndrome; sagittal sinus and upper extremity thromboses), venous thromboses in APS do not differ clinically from thromboses attributable to other causes. Similarly, arterial thromboses differ from non-aPL-associated thromboses only by their recurrent nature, unusual locations, and occurrence in young patients. Deep vein thrombosis and stroke are the most common clinical manifestations of APS. Renal thrombotic microangiopathy, glomerular capillary endothelial cell injury, and thrombosis of renal vessels cause proteinuria without cells in the urine or hypocomplementemia and may lead to severe hypertension, renal failure, or both.⁴⁶

Pregnancy Morbidity

Pregnancy losses in patients with aPLs typically occur after 10 weeks' gestation (fetal loss), although earlier losses also occur. These pre-embryonic or embryonic pregnancy losses (<10 weeks' gestation) are commonly due to chromosomal and other genetic defects. Pregnancy in those with APS is often normal until the second trimester, when fetal growth slows and amniotic fluid volume decreases. APS patients may develop severe, early preeclampsia or HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. Placental infarction is a cause of fetal growth restriction or death; nonthrombotic mechanisms of placental dysfunction also may occur.⁴⁷ Prior late pregnancy losses predict future losses, independent of the aPL profile.

Miscellaneous and Noncriteria Manifestations

Many patients have livedo reticularis or thrombocytopenia (Figure 82-2), although these conditions are not specific for

Figure 82-2 Livedo reticularis in antiphospholipid syndrome.

APS. Cardiac valve disease (vegetations, thickening, or both), a late manifestation, may necessitate valve replacement. Its pathogenesis in APS is unknown. Recent studies suggest that APS does not add to the risk of atherosclerosis imparted by SLE.⁴⁸ Pulmonary hypertension may develop owing to recurrent pulmonary embolism or small vessel thrombosis; rarely, aPL-positive patients may present with diffuse pulmonary hemorrhage. Some patients develop non-focal neurologic symptoms such as lack of concentration, forgetfulness, and dizzy spells. Multiple small, hyperintense lesions seen on magnetic resonance imaging (MRI), primarily in the periventricular white matter, do not correlate well with clinical symptoms. Rarely, high-affinity antiprothrombin antibodies may cause hemorrhage by depleting prothrombin (lupus anticoagulant hypoprothrombinemia syndrome).⁴⁹

Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare, abrupt, life-threatening complication. It consists of multiple thromboses of medium and small arteries occurring (despite apparently adequate anticoagulation) over a period of days and causing stroke; cardiac, hepatic, adrenal, renal, and intestinal infarction; and peripheral gangrene.^{4,50} In a review of 220 patients with catastrophic APS, the main clinical manifestations included renal involvement in 154 patients (70%), pulmonary in 146 (66%), cerebral in 133 (60%), cardiac in 115 (52%), and cutaneous in 104 (47%).⁵¹ Acute adrenal failure may be the initial clinical event. Proposed formal criteria for this syndrome are shown in Table 82-3.⁵² Patients often have moderate thrombocytopenia; erythrocytes are less fragmented than in the hemolytic uremic syndrome or thrombotic thrombocytopenic purpura, and fibrin split products are not strikingly elevated. Renal failure and pulmonary hemorrhage may occur. Tissue biopsies show noninflammatory vascular occlusion.

DIAGNOSIS AND DIAGNOSTIC TESTS

Laboratory Studies

The diagnosis of APS requires a positive lupus anticoagulant test or a moderate- to high-titer anticardiolipin or anti- β_2 GPI IgG or IgM test in patients with characteristic clinical manifestations. Patients with negative lupus anticoagulant

Table 82-3 Preliminary Criteria for the Classification of Catastrophic Antiphospholipid Syndrome (APS)

<ol style="list-style-type: none"> 1. Evidence of involvement of three or more organs, systems, or tissues* 2. Development of manifestations simultaneously or in less than 1 wk 3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue† 4. Laboratory confirmation of the presence of antiphospholipid antibody (lupus anticoagulant or anticardiolipin or anti-β_2-glycoprotein I antibodies)‡
Definite Catastrophic APS
All four criteria
Probable Catastrophic APS
Criteria 2 through 4 and two organs, systems, or tissues involved
Criteria 1 through 3, except no confirmation 6 wk apart owing to early death of patient not tested before catastrophic episode
Criteria 1, 2, and 4
Criteria 1, 3, and 4 and development of a third event more than 1 wk but less than 1 mo after the first, despite anticoagulation

*Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension, proteinuria, or some combination of these.

†For histopathologic confirmation, significant evidence of thrombosis must be present, although vasculitis may coexist occasionally.

‡If the patient has not been diagnosed previously with APS, laboratory confirmation requires that the presence of antiphospholipid antibody be detected on two or more occasions at least 6 wk apart (not necessarily at the time of the event), according to proposed preliminary criteria for the classification of APS.

From Asherson RA, Cervera R, de Groot PG, et al: Catastrophic antiphospholipid syndrome: international consensus statement on classification criteria and treatment guidelines, *Lupus* 12:530–534, 2003.

and anticardiolipin tests should be tested for IgA anticardiolipin and IgG, IgM, or IgA anti- β_2 GPI when there is a high suspicion for APS. Positive aPL results require a repeat test after 12 or more weeks to exclude a transient, clinically unimportant antibody. The diagnosis of APS should be questioned if less than 12 weeks or more than 5 years separate the positive aPL test from the clinical manifestation.²

The lupus anticoagulant test is a more specific but less sensitive predictor of thromboses than is anticardiolipin test; it correlates better with aPL-related clinical events.⁵³ However, both false-positive and false-negative lupus anticoagulant test results may occur in anticoagulated patients. Documentation of a lupus anticoagulant requires a four-step process: (1) demonstration of a prolonged phospholipid-dependent coagulation screening test, such as activated partial thromboplastin time or dilute Russell viper venom time (however, low-level abnormalities are not clearly linked to APS); (2) failure to correct the prolonged screening test by mixing the patient's plasma with normal platelet-poor plasma, demonstrating the presence of an inhibitor; (3) shortening or correction of the prolonged screening test by the addition of excess phospholipid, demonstrating phospholipid dependency; and (4) exclusion of other inhibitors.⁵⁴ Approximately 80% of patients with lupus anticoagulant have anticardiolipin, and 20% of patients positive for anticardiolipin have lupus anticoagulant.⁵⁵

The anticardiolipin enzyme-linked immunosorbent assay (ELISA) is sensitive but not specific for the diagnosis of APS.⁵⁶ Although the widely available ELISA test for IgG

and IgM anticardiolipin is standardized, considerable variability exists among commercial laboratories that perform the test, especially for the IgA isotype.⁵⁷ Low-titer anticardiolipin or anti- β_2 GPI, transient aPLs, and antibody to noncardiolipin phospholipids (phosphatidylserine, phosphatidylethanolamine) have no or less proven relationship to APS. ELISA tests other than anticardiolipin and anti- β_2 GPI are neither standardized nor widely accepted as predictors of clinical illness.

A false-positive test for syphilis does not fulfill the laboratory criteria, but it should alert physicians to order the aPL tests previously described, especially in patients with a history of aPL-related clinical manifestations.

Whether to test persons with venous occlusive disease or recurrent fetal loss simultaneously for protein C, protein S, and antithrombin III deficiency or for the factor V Leiden and prothrombin mutations is a matter of economics and clinical likelihood; such testing is advisable when feasible. It is useful to test persons with arterial occlusive disease for hyperhomocysteinemia.

Antinuclear and anti-DNA antibodies occur in approximately 45% of patients clinically diagnosed as having primary APS without an accompanying illness⁵⁸; these antibodies do not mandate the additional diagnosis of SLE if the patient has no clinical indicators of SLE. Thrombocytopenia in APS is usually modest ($>50,000/\text{mm}^3$); proteinuria and renal insufficiency occur in patients with thrombotic microangiopathy. Pathologic examination demonstrates small artery and glomerular thrombi and recanalization (Figure 82-3). Hypocomplementemia, erythrocyte casts, and pyuria are not characteristic of thrombotic microangiopathy and, when present, imply lupus glomerulonephritis. Erythrocyte sedimentation rate, hemoglobin, and leukocyte count are usually normal in patients with uncomplicated primary APS, except during acute thrombosis. Prothrombin fragment 1 + 2 and other markers of coagulation activation do not predict impending thrombosis.

Imaging Studies

MRI shows vascular occlusion and infarction consistent with clinical symptoms, with no special characteristics (other than multiple, otherwise unexplained cerebral infarctions in a young person). Multiple small, hyperintense white matter lesions are common and do not unequivocally imply brain infarction. Occlusions usually occur in vessels below the resolution limits of angiography; hence, angiography or magnetic resonance angiography is not indicated unless clinical findings suggest medium- or large-vessel disease. Echocardiography or cardiac MRI may show severe Libman-Sacks endocarditis and intracardiac thrombi.⁵⁹

Pathology

Skin, renal, and other tissues show thrombotic occlusion of all caliber arteries and veins, acute and chronic endothelial injury and its sequelae, and recanalization in late lesions. Uteroplacental insufficiency was once thought to be due to thrombosis or spiral artery vasculopathy (atherosis, intimal thickening, fibrinoid necrosis, and absence of physiologic changes in the spiral arteries).⁶⁰ Consistent with the importance of inflammation in murine models of APS, recent

Figure 82-3 Renal thrombotic microangiopathy in antiphospholipid syndrome (APS). **A**, Kidney biopsy from a 35-year-old woman with primary APS, microhematuria, and non-nephrotic proteinuria. The glomerulus contains microthrombi and occluding capillary lumina, and endothelial swelling is evident. **B**, The same patient's small renal artery contains organized thrombus, with recanalization and arteriosclerosis (periodic acid–Schiff, $\times 100$). **C**, Autopsy specimen from a 45-year-old man with primary APS. Note the thrombus in various stages of organization, intact elastic lamina with focal reduplication, and medial thickening (elastic Verhoeff stain, $\times 100$). **D**, The same patient's medium-sized peripheral artery. Note the organized thrombus with recanalization, severe fibrointimal thickening, medial hypertrophy, and extreme stenosis of the lumen (hematoxylin and eosin, $\times 75$). (Courtesy Dr. Surya V. Seshan.)

findings demonstrate inflammatory infiltrates, particularly macrophages, and suggest that inflammation contributes to placental injury in patients.⁶¹ The finding of necrotizing vasculitis suggests concomitant lupus or other connective tissue disease. No other diagnostic immunofluorescence or electron microscopic findings have been reported.

Differential Diagnosis

Infection-induced anticardiolipin is usually transient and is more commonly IgM than IgG.⁶² Transient aPLs or low-titer anticardiolipin is inconclusive for diagnosis. Research laboratories can distinguish autoimmune from infection-induced aPLs by determining the antibody's β_2 GPI dependence. In a patient who has lupus or lupus-like disease, livedo reticularis, or long-standing thrombocytopenia and who has a persistently positive aPL test in addition to APS-related symptoms, it is usually unnecessary to exclude other diagnoses.

Because the prevalence of aPL-positive ELISA tests increases with age, and because the differential diagnosis of vascular occlusion is broader than it is in young adults, particular care is necessary in diagnosing APS in patients older than 60 years. Sustained high-titer anticardiolipin IgG, livedo reticularis, thrombocytopenia, coexisting rheumatic disease, and absence of other causes support a diagnosis of APS.

Five percent to 21% of women with recurrent pregnancy losses, and 0.5% to 2% of normal pregnant women, have

aPLs. Heritable deficiency of protein C, protein S, and antithrombin III and the presence of the factor V Leiden (A506G), prothrombin (G20210A), and methylene tetrahydrofolate reductase (MTHFR, C677T) mutations are less common causes of fetal loss.⁶³ Attribution of pregnancy loss to APS is most certain when no coexisting plausible explanation is known, when the loss occurs after demonstration of a fetal heartbeat (10 weeks), when a significant aPL profile is repeatedly positive before and after pregnancy, and when the placenta shows vasculopathy and infarction. A single pregnancy loss before 10 weeks' gestation in a patient with a low-positive anticardiolipin test is more likely to be attributable to fetal chromosomal abnormalities, infection, or maternal hormonal or anatomic abnormalities.

Independent coagulopathies may further increase thrombotic risk in patients with aPLs. These and other acquired thrombotic risk factors (hypertension, diabetes, nephrotic syndrome, venous insufficiency, immobility) are alternative causes of thromboembolic disease. Arterial occlusion occurs in patients with thrombotic thrombocytopenic purpura, infected or sterile emboli of cardiac or vascular origin, septicemia, hyperhomocysteinemia, myxoma, Takayasu's arteritis, polyarteritis nodosa, and severe Raynaud's disease. The relationship of Sneddon's syndrome (stroke and livedo reticularis, with or without aPLs) to APS is uncertain.

Catastrophic APS has few mimics. Among them are sepsis, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome,

polyarteritis nodosa, and disseminated embolization from myxoma, atrial thrombus, or atherosclerotic plaque. Small vessel occlusions occurring in rapid succession suggest disseminated intravascular coagulation. Severe cerebral and renal disease suggests thrombotic thrombocytopenic purpura; renal failure and hemolysis suggest hemolytic uremic syndrome. Antiphospholipid antibodies are rarely present in patients with the alternative diagnoses. Acute adrenal insufficiency is characteristic of APS and Waterhouse-Friderichsen syndrome.

TREATMENT

Thrombosis

Treatment recommendations are summarized in Table 82-4. Anticoagulation with heparin is the treatment for acute thrombosis in APS patients. Warfarin, occasionally in association with low-dose aspirin, is used for secondary thrombosis prophylaxis. Two randomized, controlled trials demonstrated that moderate warfarin (international normalized ratio [INR], 2 to 3) and high-intensity warfarin (INR, 3 to 4) are equally protective against recurrence in APS patients after the first thrombosis.^{64,65} The intensity of anticoagulation for aPL-related arterial thrombosis is still a matter for debate because in both studies, patients with arterial events constituted less than half of the study

population. Although APS patients with arterial thrombosis who are at high risk for recurrence may require high-intensity anticoagulation, in the absence of risk-stratified studies, *high risk* has no consensus definition and currently is based solely on clinical judgment.

Aspirin is the standard of care after an ischemic stroke or a transient ischemic attack to prevent a recurrence in aPL-negative patients. Although most aPL-positive patients with ischemic strokes receive warfarin, the Antiphospholipid Antibody in Stroke Study (APASS) concluded that for selected aPL-positive patients who do not have atrial fibrillation or high-grade stenosis, aspirin and warfarin (target INR, 2.2) are equivalent in terms of both efficacy and major bleeding complications.⁶⁶ The APASS results probably do not apply to conventionally defined APS because the average age of study participants was much higher than that of the average APS population; in addition, the aPL determination was performed only once at study entry, and the titer cutoff for assigning a patient to the positive anticardiolipin group was very low. However, aspirin is an option for older aPL-positive patients who have a single low-titer anticardiolipin test, and whose presentation is one stroke.

Some patients require larger than expected doses of both heparin and warfarin to achieve therapeutic anticoagulation. Uncommonly, positive lupus anticoagulant tests cause the INR to be unreliable.⁶⁷ Patients with constantly fluctuating INR levels and/or recurrent events despite therapeutic INR may be monitored by the measurement of anti-factor Xa activity or another appropriate assay.

For well-anticoagulated patients who continue to have thromboses, the addition of aspirin (81 to 325 mg/day) can be considered. Experimental (in vitro and/or animal models) and clinical evidence (in lupus patients) suggests that hydroxychloroquine may decrease the incidence of thrombosis; similarly, experimental evidence indicates that statins can interfere with aPL-mediated thrombosis.⁶⁸ However, controlled studies are needed to determine the effectiveness of hydroxychloroquine and statins in aPL-positive patients. Corticosteroids have no established role in the treatment of APS but are used for rheumatic symptoms in patients with accompanying systemic autoimmune illness. However, high doses of corticosteroids usually are given empirically to patients with severe thrombocytopenia, hemolytic anemia, and catastrophic APS.

No controlled studies in APS patients have been published for clopidogrel, pentoxifylline, aspirin-dipyridamole, argatroban, hirudin, and other new anticoagulant agents. Neither hirudin nor fondaparinux inactivates complement, and neither drug protects mice with experimental APS against pregnancy loss, so they may be ineffective in human disease. Clinical experience suggests that thrombolytic agents for acute thrombosis are unhelpful because reocclusion occurs rapidly.

Currently available data, although retrospective and not risk-stratified, indicate that lifelong anticoagulation of APS patients who have had vascular events is appropriate.⁶⁹ However, recent recognition that some patients have full remission of antibody, and that most thrombotic events have recognizable triggers, raises the possibility of discontinuing anticoagulation in highly selected patients when the triggers are eliminated.

Table 82-4 Treatment Recommendations for Persistently Antiphospholipid Antibody–Positive Individuals

Clinical Circumstance	Recommendation
Asymptomatic	No treatment*
Venous thrombosis	Warfarin INR 2.5 indefinitely
Arterial thrombosis	Warfarin INR 2.5 indefinitely
Recurrent thrombosis	Warfarin INR 3-4 ± low-dose aspirin
Pregnancy:	
First pregnancy	No treatment†
Single pregnancy loss at <10 wk	No treatment†
≥1 Fetal or ≥3 (pre-)embryonic losses, no thrombosis	Prophylactic heparin‡ + low-dose aspirin throughout pregnancy, discontinue 6-12 wk postpartum
Thrombosis regardless of pregnancy history	Therapeutic heparin§ or low-dose aspirin throughout pregnancy, warfarin postpartum
Valve nodules or deformity	No known effective treatment; full anticoagulation if emboli or intracardiac thrombi demonstrated
Thrombocytopenia >50,000/mm ³	No treatment
Thrombocytopenia <50,000/mm ³	Prednisone, IVIG
Catastrophic antiphospholipid syndrome	Anticoagulation + corticosteroids + IVIG or plasmapheresis

*Aspirin (81 mg/day) may be considered in high-risk patients with multiple non-aPL cardiovascular risk factors.

†Aspirin (81 mg/day) may be considered.

‡Enoxaparin 0.5 mg/kg subcutaneously once daily.

§Enoxaparin 1 mg/kg subcutaneously twice daily or 1.5 mg/kg subcutaneously once daily.

INR, international normalized ratio; IVIG, intravenous immunoglobulin.

Pregnancy Morbidity

Heparin is indicated at the diagnosis of pregnancy in an aPL-positive woman who has had prior pregnancy losses attributable to APS. Because warfarin is teratogenic, only unfractionated or low-molecular-weight heparin is used for the treatment of affected pregnancies in the United States; in other countries, converting to warfarin after the first trimester may be considered acceptable.⁷⁰ Most physicians with a special interest in this field now use low-molecular-weight heparin owing to decreased risk of thrombocytopenia and osteoporosis.

Patients with prior fetal losses later than 10 gestational weeks should be treated with prophylactic heparin (enoxaparin 30 to 40 mg subcutaneously once daily), together with low-dose aspirin; this regimen increases the fetal survival rate from 50% (untreated) to 80%.^{71,72} Women who have had prior thromboses must be fully anticoagulated (enoxaparin 1 mg/kg subcutaneously twice daily or 1.5 mg/kg subcutaneously once daily) throughout pregnancy because the risk of new thrombosis markedly increases both during pregnancy and during the postpartum period. Even with treatment, prematurity and fetal growth restriction may occur. Clopidogrel and newer antithrombotic agents have not been cleared for use in pregnancy but, together with intravenous immunoglobulin (IVIG) and hydroxychloroquine, they may be considered in patients who are unable to use heparin, or who fail heparin treatment.

In aPL-positive women with prior thrombosis, warfarin is changed to heparin or low-molecular-weight heparin before conception, if possible, or at the first missed menstrual period. In aPL-positive women without prior thrombosis, if heparin is indicated during pregnancy, treatment begins after confirmation of pregnancy, continues until 48 hours before anticipated delivery (to allow epidural anesthesia), and resumes for 8 to 12 weeks during the postpartum period. Some physicians recommend the initiation of heparin before conception; no clinical trial supports this recommendation, however, and the risk associated with longer-duration heparin therapy is considerable. Patients in most published series received low-dose aspirin as well as heparin, but the benefit of adding aspirin is unknown.

Because of the risk of postpartum thrombosis, it is prudent to continue anticoagulation for 8 to 12 weeks during the postpartum period and then to discontinue it by tapering the doses. If desired, conversion from heparin to warfarin may be accomplished after the first or second postpartum week. Breastfeeding is permissible with both heparin and warfarin.

No studies unequivocally justify the treatment of women with aPLs during a first pregnancy, women with only very early losses, or women whose aPL titers are low or transient. Nonetheless, it is common to offer such patients low-dose aspirin.

Asymptomatic Antiphospholipid Antibody-Positive Individuals

Persistence of aPLs for decades without clinical events is well documented. The probability that an asymptomatic person incidentally found to have aPLs will eventually develop the syndrome is likely low.⁷ Anticoagulation is not

indicated for the prophylactic treatment of asymptomatic aPL-positive individuals. For those with moderate- to high-titer anticardiolipin and persistent aPLs, education about the meaning of abnormal tests is appropriate, as is a discussion of warning signs to be reported. Elimination of reversible thrombosis risk factors and prophylaxis during high-risk periods, such as surgical procedures, are crucial. The necessity for and the effectiveness of aspirin are not supported by the current literature; in a recent randomized, double-blind, placebo-controlled trial, low-dose aspirin (81 mg) appeared to be no better than placebo in preventing first thrombotic episodes in persistently asymptomatic aPL-positive patients; the incidence rate of first thrombosis was relatively low.⁹

Although drugs that induce lupus (hydralazine, phenytoin) may also induce aPLs, they may be prescribed for patients with aPLs if no alternatives are available. Drugs that promote thrombosis (estrogen and estrogen-containing oral contraceptives) are not currently deemed safe, even for asymptomatic women serendipitously known to have high-titer antibodies. This advice does not translate to a recommendation to test all normal women before prescribing such medications, but it does suggest that special attention and further evaluation should be provided to those with family histories or clinical suggestions of rheumatic disease, livedo reticularis, biologic false-positive tests for syphilis, or borderline thrombocytopenia. No reliable information is available regarding the safety of progestin-only contraception, “morning after” contraception, or the use of raloxifene, bromocriptine, or leuprolide in APS patients. A small retrospective review of women undergoing artificial reproductive technology (in vitro fertilization) procedures demonstrated no thrombotic events.⁷³

Antiphospholipid Antibody-Positive Individuals with Ambiguous Events

Some patients with positive aPL tests have clinical events of ambiguous meaning (dizzy or confusional episodes, non-specific visual disturbances, very early pregnancy loss). No consensus has been reached regarding the treatment of such persons. Because full anticoagulation carries high risk, many physicians prescribe low-dose (81 mg) aspirin, hydroxychloroquine, or both daily. No published data support or repudiate this recommendation. Based on the presumed pathogenesis, some physicians prescribe anticoagulation for patients with livedo reticularis, thrombocytopenia, leg ulcers, thrombotic microangiopathy, or valvulopathy. The efficacy of anticoagulation is unknown in these conditions. One small, descriptive, cross-sectional study provides evidence that B cell depletion with rituximab is well tolerated and can be effective for refractory thrombocytopenia and skin ulcers in aPL-positive patients.⁷⁴ An open-label phase IIa descriptive pilot study assessing the effectiveness and safety of rituximab in patients with noncriteria and/or anticoagulation-resistant manifestations of aPL is in progress (Clinical Trials.gov Identifier: NCT00537290).

Catastrophic Antiphospholipid Syndrome

The onset of catastrophic APS is usually sudden and immediately life threatening. Early diagnosis can be a challenge, especially in patients with no history of APS. However,

early diagnosis is critical because, in contrast to other causes of multiple organ dysfunction syndrome, appropriate therapy includes anticoagulation and corticosteroids in combination with repeated plasma exchange, IVIG, and, in desperate situations, other modalities such as cyclophosphamide or rituximab. However, mortality remains as high as 48% despite all attempts at effective therapy.⁷⁵ No systematic studies have examined the treatment of catastrophic APS owing to the rarity of the condition.

Antiphospholipid Antibody–Negative Individuals with a Clinical Event

In patients clinically suspected of having APS but with normal anticardiolipin, lupus anticoagulant, and anti- β_2 GPI tests, alternative causes of clotting must be sought. Even among patients with concomitant rheumatic disease, APS may not be the cause of recurrent thromboembolism or pregnancy loss. Patients with SLE develop emboli from SLE-related cardiac valvular disease, vasculitis, or atheroma. Other patients have factor V Leiden or some other procoagulant mutation. Recurrent pregnancy losses may be caused by chromosomal abnormalities, uterine infection, diabetes, hypertension, or non-aPL coagulopathy. The concept of “seronegative” APS is not recognized.

OUTCOME

Pulmonary hypertension, neurologic involvement, myocardial ischemia, nephropathy, gangrene of extremities, and catastrophic APS are associated with a worse prognosis. During long-term follow-up, serious morbidity and disability occur in an unpredictable proportion of primary APS patients who experience major vascular events and in those who have delays in diagnosis and treatment. Thus, the long-term functional outcome of primary APS patients is poor; at 10 years, one-third of patients develop permanent organ damage, and one-fifth are unable to perform everyday activities.⁷⁶

In a retrospective study of obstetric APS patients without thrombosis, 35% developed aPL-related clinical events during 8 years of follow-up⁷⁷. The studied populations were highly selected referral populations that may have been biased toward severe disease, but follow-up studies of obstetric patients with autoantibodies show similar results.⁷⁸

Long-term outcomes of children born of APS pregnancies are not known. In many patients with long-standing APS, the development of severe cardiac valvular disease necessitates valve replacement, and rare patients develop renal failure due to thrombotic microangiopathy. Immediate thrombosis may cause loss of a transplanted kidney or other organ; aPL positivity correlates with poor graft survival after renal transplantation in SLE patients.⁷⁹

Serious perioperative complications may occur despite prophylaxis in aPL-positive patients because they are at additional risk for thrombosis when undergoing surgical procedures. Thus perioperative strategies should be clearly identified before any surgical procedure is performed; in addition, pharmacologic and physical antithrombosis interventions should be vigorously employed, periods without anticoagulation should be kept to an absolute minimum, intravascular manipulation for access and monitoring

should be minimized, and any deviation from a normal course should be considered a potential disease-related event.⁸⁰

Etiology and Pathogenesis of Scleroderma

JOHN VARGA

KEY POINTS

Scleroderma/systemic sclerosis (SSc) has a complex pathogenesis and protean clinical manifestations reflecting the underlying early immune dysregulation and microangiopathy, as well as subsequent systemic fibrosis.

There is marked patient-to-patient variability in clinical and laboratory manifestations, disease course, and molecular signatures, suggesting the existence of distinct disease subsets.

Vascular lesions in small blood vessels occur early and progress to obliterative vasculopathy that causes tissue hypoxia, oxidative stress, and vascular complications.

Immune dysregulation manifested by autoantibodies, evidence of innate immune activation, and the “interferon signature” is prominent in SSc, but its role as a primary factor in pathogenesis has not been established. Genetic association studies implicate the human leukocyte antigen (HLA) and other immunoregulatory genes that are also associated with systemic lupus erythematosus.

Fibrosis is associated with sustained mesenchymal cell activation by growth factors, cytokines, chemokines, hypoxia and reactive oxygen species, and aberrant reactivation of developmental pathways.

Scleroderma or systemic sclerosis (SSc) is an uncommon disease of unknown cause and complex pathogenesis. The hallmarks of SSc are (1) autoimmunity, (2) inflammation, (3) functional and structural alterations in small blood vessels, and (4) interstitial and vascular fibrosis in the skin and internal organs. This unique constellation of distinct but related pathophysiologic features, illustrated in [Figure 83-1](#), accounts for the characteristic clinical manifestations of SSc. Early-stage disease may be dominated by inflammation and vascular injury, whereas in advanced disease fibrosis and vascular insufficiency are most prominent. However, there is enormous patient-to-patient variability in these features. Recent advances in cell and molecular biology, mouse genetic engineering, functional genomics, and genetic

association studies reveal the involvement of a large number of molecules, pathways, and cell types in SSc, yielding an increasing nuanced picture of the pathogenesis. Environmental triggers in a genetically susceptible individual are thought to induce a cascade of events with early vascular injury, immune cell activation, the generation of autoimmunity, and subsequent fibroblast activation and matrix accumulation that results in chronic and progressive tissue damage. Over time, vascular insufficiency and widespread fibrosis cause disruption of vital organs, accounting for the substantial morbidity and mortality of SSc.

ETIOLOGY

Neither the cause of SSc nor the precise contribution of genetic factors is fully understood. Evidence indicates that infectious agents, environmental toxins, and drugs, as well as microchimerism, are potential triggers.

Genetic Risk: Family Studies

Familial clustering of a disease is considered as evidence of inherited disease susceptibility, but such clustering might be explained by shared environmental exposures, shared genetic background, or the interaction between genes and environment.¹ The risk of SSc is increased among first-degree relatives of SSc cases compared with the general population. In one U.S. study, the relative risk of SSc among first-degree relatives of cases was 13, with a rate of 1.6% compared with 0.026% in the general population, identifying a family history of SSc as the strongest known risk factor.² The only twin study of SSc to date reported a relatively small disease concordance rate (4.7%), although the concordance rate for positive antinuclear antibody (ANA) was 90% for monozygotic (identical) twins and 40% for dizygotic (fraternal) twins.³ Raynaud disease and pulmonary fibrosis show increased prevalence in pedigrees of SSc patients.⁴ Moreover, autoimmune diseases among first-degree family members of SSc patients have been reported in up to 36% of cases, with hypothyroidism, hyperthyroidism, rheumatoid arthritis, and systemic lupus erythematosus (SLE) most common.

Figure 83-1 The pathophysiologic quartet underlying systemic sclerosis. Patients with systemic sclerosis display evidence of inflammation, autoimmunity, vasculopathy, and fibrosis. Autoimmunity and vasculopathy generally precede the onset and contribute to the progression of fibrosis. Vascular obliteration and interstitial fibrosis perpetuate and further exacerbate chronic autoimmunity and inflammation. (Courtesy Kathleen Kelley.)

Genetic Association Studies: Immune Susceptibility Genes for Scleroderma

The past decade has witnessed rapid progress in delineating genetic susceptibility factors in SSc. Genetic association studies using candidate gene approaches and, more recently, genome-wide association (GWA) studies have been performed in large multinational patient cohorts. The major histocompatibility complex (MHC) is the dominant genetic region implicated in autoimmune disease, although the role of specific human leukocyte antigen (HLA) alleles in pathogenesis remains unknown. The interpretation of HLA associations is complicated by the extensive linkage disequilibrium of risk haplotypes. Specific HLA alleles have long been known to be associated with SSc and specific autoantibodies. For instance, a case-control study of SSc revealed strong associations with HLA DRB1*1104, DQA1*0501, and DQB1*0301 haplotypes.⁵ Candidate gene approaches typically look for changes in single nucleotides (single nucleotide polymorphisms [SNPs]), the most common form of deoxyribonucleic acid (DNA) variation. Non-HLA susceptibility genes associated with SSc include the protein tyrosine phosphatase nonreceptor 22 (PTPN22), which has been associated with SLE, myasthenia gravis, vitiligo, and Addison's disease; interleukin (IL)-1 β and NLRP1, an inflammasome scaffold that promotes pro-IL-1 β maturation and processing; and interferon regulatory factor 5 (IRF5), a transcription factor in the Toll-like receptor

(TLR) pathway that mediates type I interferon (IFN) induction and is associated with SLE, as well as SSc and interstitial lung disease. The association of IRF5 with SSc is particularly interesting, in light of the role of IFN type I in immune responses. Table 83-1 summarizes SSc susceptibility genes identified to date. In addition to classic SNPs, informative genetic polymorphisms in SSc include variations of copy numbers, rare allelic variants, and epigenetic changes. The identification of these genetic associations will require in-depth analysis using deep-sequencing technologies.

Other Candidate Genes and Genome-wide Association Studies

Candidate gene approaches focusing on genes involved in vascular homeostasis or matrix remodeling have to date not yielded robust associations with SSc. A British study identified a functional SNP in the connective tissue growth factor (CTGF) promoter region associated with SSc. However, in another study an apparent association with SPARC could not be validated in an independent cohort. Potential explanations for discrepancies among genetic association studies include ethnic differences in the study populations and disease heterogeneity.

Several GWA studies in large and ethnically diverse populations are currently under way. These unbiased approaches have the advantage over candidate gene studies in that they are driven by discovery rather than a priori hypotheses. The first large-scale SSc GWA study analyzed 300,000 SNPs in a cohort of 2296 white cases and 5014 healthy controls.⁶ Statistically significant associations were found with SNPs in the HLA region, as well as *IRF5*, *TNFAIP3*, and *CD247*, a gene implicated in T cell signaling and also associated with susceptibility to SLE. Although genetic association studies represent a rapidly evolving area of research, the results to date can be summed up as follows: (1) Genetic variants associated with SSc susceptibility are involved in innate and adaptive immune responses, and (2) they are shared with SLE and other autoimmune diseases. It is worth noting that important associations can be missed by GWA studies using current technologies. Moreover, despite the wealth of emerging information, the genetic associations discovered to date are of relatively modest magnitude, with odds ratios that are generally less than 1.5. This finding points to the potential importance of gene-gene interactions (epistasis), particularly for genes within the same molecular pathways, and gene-environment

Table 83-1 Systemic Sclerosis (SSc) Susceptibility Genes

Locus	Chromosome	Associated SSc Subset	Potential Pathogenic Mechanism
HLA	6	Various	Antigen presentation
PTPN22	1p3.2	Topo1+ positive	T and B cell activation
NLRP1	17p13.2	dcSSc, pulmonary fibrosis	Inflammasome component, IL-1 β processing
IRF5	7q32	dcSSc	Transcription factor required for induction of type I interferon
STAT4	2q32.3	lcSSc, ACA	Transcription factor for IL-12 and IL-23
BANK1	4q24	dcSSc	Adaptor involved in B cell signaling
TNFSF4	1q25	SSc	T cell co-stimulation
T-bet	17.q21.32	SSc	Transcription factor for Th1 T cell polarization

Based on published candidate gene studies and genome-wide association studies as of 2011.

ACA, anticentromere antibody; dcSSc, diffuse cutaneous SSc; IL, interleukin; lcSSc, limited cutaneous SSc; SSc, systemic sclerosis.

interactions. A current challenge in SSc research is how to handle the large volume of new information emerging from GWA studies. Moreover, it will be important to delineate how genes shared among diverse autoimmune conditions contribute to disease-specific phenotypes. Shedding light on this important problem will require large collaborative studies involving phenotypically well-characterized populations of varied ethnic background and meta-analyses.

INFECTIOUS AGENTS: VIRUSES

Along with exposure to certain environmental and occupational agents and drugs, viruses such as human cytomegalovirus (hCMV) and parvovirus B19 have been implicated as potential triggers for SSc. Patients with SSc have anti-hCMV antibodies directed against the UL83 and UL94 protein epitopes on hCMV. Anti-UL94 antibodies can induce endothelial cell apoptosis and fibroblast activation, suggesting a direct role for antiviral antibodies in tissue damage. Antitopoisomerase-I can cross-react with hCMV-derived proteins, implicating molecular mimicry as a mechanism linking hCMV infection and SSc.⁷ Cytomegalovirus is implicated in the pathogenesis of allograft vasculopathy, a complication of organ transplantation characterized by vascular neointima formation and smooth muscle cell proliferation strikingly reminiscent of the obliterative proliferative vasculopathy seen in SSc. In dermal fibroblasts, hCMV stimulates synthesis of the profibrotic growth factor connective tissue growth factor (CTGF, CCN2) in vitro.⁸ Evidence of human parvovirus B19 infection has also been reported in patients with SSc.

ENVIRONMENTAL EXPOSURES, DIETARY SUPPLEMENTS, DRUGS AND RADIATION

Although reports of putative geographic clustering suggest a role for shared environmental exposures, careful investigations have generally failed to substantiate apparent clusters of SSc. On the other hand, well-documented epidemic outbreaks of SSc-like illnesses with acute onset and chronic course have been reported. One such illness, called the *toxic oil syndrome*, occurred in Spain and was linked to the ingestion of contaminated rapeseed cooking oils.⁹ In the United States, dietary supplements containing L-tryptophan were implicated in an explosive outbreak of the eosinophilia-myalgia syndrome (EMS) in 1989.¹⁰ The EMS epidemic subsided following the ban on L-tryptophan, but sporadic cases of EMS following ingestion of L-tryptophan and other food supplements continue to be reported. Although scleroderma-like skin fibrosis was a prominent manifestation of these apparently de novo toxic epidemic syndromes, along with multisystem involvement, chronic course, and autoimmunity, the associated clinical, histopathologic, and laboratory features clearly differentiate them from SSc.¹¹ The frequency of SSc appears to be increased among men with occupational exposure to silica dust. This was recently confirmed by a meta-analysis of 16 observational studies, with risk estimates as high as 15.¹² Other exposures linked with SSc include polyvinyl chloride, toluene, xylene, trichloroethylene, and organic solvents. Additional reports

alleged an association between SSc and environmental exposures to pesticides, hair dyes, and industrial fumes. Although exposure to cigarette smoke is known to increase the risk of multiple autoimmune diseases, there is no evidence to date implicating it as a risk factor for SSc.

Certain drugs have been implicated in SSc-like illnesses. The best studied is the anticancer drug bleomycin, which induces skin and lung fibrosis in the mouse (see later). Other potentially implicated drugs include pentazocine, the taxenes docetaxel and paclitaxel, and cocaine. The use of appetite suppressants has been linked to the development of pulmonary arterial hypertension (PAH). The occurrence of SSc in women following cosmetic breast augmentation with silicone implants raised significant concern regarding a possible causal association.¹³ Subsequent large-scale epidemiologic surveys and a meta-analysis, however, failed to confirm an increased risk of SSc or of other connective tissue diseases among women with silicone breast implants.¹⁴ Radiation treatment for malignant neoplasms has been linked with the onset of de novo SSc, as well as exacerbation of tissue fibrosis in patients with pre-existing SSc.¹⁵ Some of the environmental agents and drugs that have been linked with the development of SSc are listed in Table 83-2.

MICROCHIMERISM

Healthy women harbor immunologic stem cells of fetal origin that persist for many years following pregnancy, a condition called *microchimerism*. Some studies found that the number of circulating fetal cells is elevated in women with SSc compared with healthy women.^{16,17} Moreover, cells with a male chromosome, presumably from a prior pregnancy with a male fetus, have been detected in affected organs from women with SSc. It has been speculated that persistence of fetal cells in SSc may be linked to the development of the disease through a graft-versus-host response triggered by the fetal cells or through a maternal (auto) immune response against the fetal cells.

PATHOLOGY

General Features

The pathologic hallmarks of SSc are a noninflammatory proliferative/obliterative vasculopathy affecting small arteries and arterioles in multiple vascular beds and interstitial and vascular fibrosis, most prominent in the skin, lungs, and heart.¹⁸ Inflammation is generally absent in long-standing SSc, but in early-stage disease inflammatory cell infiltrates in many organs may be prominent. In the skin, the infiltrates are located predominantly around blood vessels and in the reticular dermis and are composed primarily of CD4⁺ T lymphocytes and monocytes, whereas in the lungs, cellular infiltrates consist predominantly of CD8⁺ T lymphocytes.

Vascular Pathology

Vascular injury and activation are the earliest and possibly primary events in SSc. Histopathologic evidence of vascular damage is present before fibrosis and can be detected in involved and uninvolved skin, indicating a generalized process.¹⁹ Raynaud phenomenon and other vascular manifestations typically precede other manifestations of SSc. Additional signs of vasculopathy include cutaneous telangiectasia; nailfold capillary changes (giant capillaries, hemorrhages, and avascular areas); PAH; digital tip pitting; gastric antral vascular ectasia (also called *watermelon stomach*); and scleroderma renal crisis. The most characteristic histopathologic finding in the small and medium-sized arteries is bland intimal proliferation (Figure 83-2). Intimal hypertrophy, a finding that SSc shares with chronic allograft arteriopathy, is thought to result from proliferation and migration of myointimal cells and local accumulation

Figure 83-2 Histologic appearance of systemic sclerosis vasculopathy. A pulmonary arteriole showing extensive medial hypertrophy and intimal thickening, leading to narrowing of the vascular lumen.

of collagen.²⁰ The vascular basement membranes are thickened and reduplicated. These changes are most prominent in blood vessels of the heart, lungs, kidneys, and gastrointestinal tract. A systematic survey of SSc skin biopsies revealed a marked reduction in the number of capillaries (rarefaction) and loss of vascular endothelial cadherin, a molecule required for vascular tube formation.²¹ Remarkably, this study showed that clinical improvement following high-dose immunosuppressive therapy was accompanied by capillary regeneration in the skin.

Impaired fibrinolysis, increased levels of von Willebrand factor, and ongoing platelet aggregation are prominent. Endothelial cell injury itself causes further platelet aggregation, release of platelet-derived growth factor (PDGF) and endothelin-1 (ET-1), and endothelial cell apoptosis.²² Vasculitic lesions and immune complex deposition in the vessel walls are uncommon. In late stages of the disease, extensive fibrin deposition and perivascular fibrosis cause progressive luminal occlusion, and eventually there is striking paucity of small blood vessels and capillaries in lesional tissue.²³ Loss of vascular supply leads to chronic tissue hypoxia. Widespread proliferative/obliterative vasculopathy of small and medium-sized arteries and capillary rarefaction are the pathologic hallmarks of all forms of SSc. In patients with SSc-associated PAH, pulmonary arteriolar intimal proliferation and evidence of veno-occlusive disease are prominent, whereas in contrast to idiopathic PAH, plexogenic arteriopathy does not occur.²⁴

Tissue Fibrosis

Fibrosis is characterized by excessive accumulation of fibrillar collagens, fibronectin, elastin, proteoglycans, cartilage oligomeric matrix protein (COMP), and many other structural extracellular matrix (ECM) molecules. The process causes disruption and, ultimately, complete obliteration of tissue architecture. Most prominently affected are the lungs, gastrointestinal tract, heart, tendon sheath, and perivascular tissue surrounding skeletal muscle. Histopathologic examination of these organs shows homogeneous and relatively acellular connective tissue with thick hyalinized collagen bundles.

ORGAN-SPECIFIC PATHOLOGIC FINDINGS

Skin

Fibrosis of the skin, the hallmark of SSc, is accompanied by marked expansion of the dermis with obliteration of the hair follicles, sweat glands, and sebaceous glands and other skin appendages. Collagen fiber accumulation is most prominent in the reticular (deep) dermis and progressively invades the subjacent adipose layer with entrapment of fat cells. Early-stage SSc skin biopsies reveal dermal edema and perivascular infiltrates composed of T lymphocytes and monocytes (Figure 83-3). Less commonly, mast cells and eosinophils may also be detected.^{25,26} The proportion of α -smooth muscle actin–positive myofibroblasts, a mesenchymal cell type that is intermediate between fibroblasts and contractile smooth muscle cells and plays a major role in fibrogenesis, is increased in the lesional skin.²⁷ With

Figure 83-3 Histology of skin in diffuse cutaneous systemic sclerosis. There is perivascular infiltration in the dermis with inflammatory cells of multiple lineages. Microvascular endothelial cell activation and increased extracellular matrix deposition are also seen (A). Later there is regression of the inflammatory features. Secondary structures within the skin such as hair follicles and sebaceous and sweat glands are reduced, and rete pegs are flattened (B). H&E stain, original magnification $\times 40$.

disease progression, the skin undergoes atrophy with loss of epidermal-dermal ridges and effacement of the rete pegs reminiscent of the changes seen in aging skin. The fibrotic dermis is largely acellular and contains dense accumulation of compact hyalinized collagen bundles, fibronectin, hyaluronic acid, and other structural proteins. Sweat glands and eccrine glands atrophy with loss of periglandular adipose tissue. The subcutaneous adipose layer is obliterated. In a double-blind study of 45 SSc skin biopsies, the histologic grade of skin fibrosis was found to closely correlate with the extent of clinical skin involvement.²⁸ Reduction in the number of dermal lymphatic vessels, which can be marked, contributes to interstitial fluid accumulation and edema.²⁹ Paucity of dermal capillaries (rarefaction) is associated with chronic tissue hypoxia that induces angiogenic factors such as vascular endothelial growth factor (VEGF). Evidence of tissue hypoxia can even be found in clinically uninvolved, apparently “normal” skin.³⁰

Biochemical analysis shows that the collagens in the fibrotic dermis are normal, and relative proportions of the main fibrillar collagens (type I and type III) are comparable with those of normal skin.³¹ In contrast, the minor nonfibrillar type VII collagen, normally restricted to the dermal-epidermal basement membrane zone, is abundant throughout the lesional dermis. The enzymes mediating post-translational collagen modification such as lysyl hydroxylase (PLOD2) are elevated, resulting in an increase in aldehyde-derived collagen cross-links, which may account for the dense sclerotic nature of the fibrotic dermis.³²

Genome-wide expression profiling of lesional skin using DNA microarray technology provides an increasingly clearer understanding of the activation events that underlie fibrosis. Results from several studies reveal strikingly altered gene expression patterns in SSc skin biopsies compared with healthy controls. Remarkably, clinically involved and uninvolved skin appear to be indistinguishable in terms of their gene expression profiles. Many genes involved in ECM homeostasis and in transforming growth factor- β (TGF- β),

CCN2, IL-13, and Wnt signaling pathways show elevated expression.^{33,34} Furthermore, a number of genes reflecting a bone/cartilage phenotype are elevated in the skin. A particularly intriguing finding from these studies is that skin biopsies from different individuals show marked heterogeneity at the level of their “molecular signature,” with at least five distinct and reproducible patterns identified to date.³⁵

Lungs

In early-stage SSc, the lungs show patchy infiltration of the alveolar walls with lymphocytes, plasma cells, macrophages, and eosinophils (Figure 83-4). At this stage, bronchoalveolar lavage fluid contains elevated proportions of inflammatory leukocytes. With progression, interstitial lung fibrosis

Figure 83-4 Histologic appearance of the lung. Evidence of interstitial lung disease is common in systemic sclerosis. Although there is substantial variation in the appearance of lung histology, consistent features include reduction in air spaces and thickening of alveolar walls with matrix deposition. Inflammatory cell infiltrates may be prominent. Lung biopsy is rarely required for diagnosis.

and vascular damage predominate, often coexisting within the same lesions. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies PAH and at autopsy is often associated with multiple pulmonary emboli and myocardial fibrosis.

Lung fibrosis in SSc is characterized by expansion of the alveolar interstitium due to accumulation of collagens and other connective tissue proteins. The typical histologic pattern is nonspecific interstitial pneumonitis (NSIP), a form of interstitial lung disease characterized by mild to moderate interstitial inflammation, type II pneumocyte hyperplasia, and fairly uniform distribution of fibrosis. Less commonly, SSc is associated with the usual interstitial pneumonia (UIP) pattern that is characterized by scattered fibroblastic foci and patchy distribution of fibrosis and has a worse prognosis.³⁶ Progressive alveolar septal thickening ultimately results in obliteration of the air spaces and honeycombing, as well as consequent loss of pulmonary blood vessels. This process impairs gas exchange and contributes to worsening of pulmonary hypertension. Extensive pulmonary fibrosis may also predispose to primary lung carcinoma.

Gastrointestinal Tract

Prominent pathologic changes can occur at any level from the mouth to the rectum. The esophagus is virtually always affected, with fibrosis in the lamina propria, submucosa, and muscular layers and characteristic vascular lesions.³⁷ Replacement of the normal intestinal architecture results in disordered peristaltic activity, gastroesophageal reflux and small bowel dysmotility, pseudo-obstruction, and bacterial overgrowth. Chronic gastroesophageal reflux is complicated by esophageal inflammation, ulcerations, and stricture formation. Up to one-third of SSc patients with severe gastroesophageal reflux develop Barrett's esophagus, characterized by metaplasia of the normal squamous lining of the esophagus into columnar epithelium.³⁸ Because Barrett's metaplasia is a premalignant lesion associated with a greater than 30-fold increased risk of adenocarcinoma, patients with Barrett's esophagus need ongoing monitoring for dysplasia and adenocarcinoma.

Kidneys

In the kidneys vascular lesions predominate, and glomerulonephritis is rare except in overlap syndromes. Chronic renal ischemia is associated with shrunken glomeruli and other ischemic changes. Patients with acute scleroderma renal crisis show a thrombotic microangiopathy that is indistinguishable from other forms of malignant hypertension.³⁹ Histopathologic changes are most prominent in the small interlobular and arcuate renal arteries, which show reduplication of elastic lamina, marked intimal proliferation (onion skinning), and fibrinoid necrosis of the arteriolar walls.⁴⁰ Similar pathologic changes have also been reported in SSc patients who do not have renal crisis. Intimal thickening leads to severe narrowing and total obliteration of the lumen, often with microangiopathic hemolysis. Tubular changes such as flattening and degeneration of tubular cells occur secondary to vascular insufficiency. The clinical picture of scleroderma renal crisis may resemble thrombotic

thrombocytopenic purpura (TTP). However, reduced to absent levels or activity of von Willebrand factor cleaving protease (*ADAMTS13*) has not been reported in scleroderma renal crisis. [Figure 83-5](#) shows the characteristic histologic features associated with scleroderma renal crisis.

Heart

At autopsy, evidence of cardiac involvement is found in up to 80% of patients with SSc.⁴¹ Modest pericardial effusions are common; occasionally fibrosis and constrictive pericarditis may occur. A characteristic pathologic finding is myocardial contraction band necrosis, which is thought to reflect repeated episodes of ischemia-reperfusion due to "myocardial Raynaud phenomenon."⁴² Significant interstitial and perivascular fibrosis in the heart may occur in the absence of clinically evident heart involvement. Skeletal muscle myositis in SSc is occasionally accompanied by acute myocarditis.⁴³

PATHOLOGIC FINDINGS IN OTHER ORGANS

Fibrosis of the thyroid glands is common. Broad bands of fibrous tissue are seen in the thyroid gland, with atrophy and obliteration of the follicles, in the absence of inflammation. Abnormal thyroid function tests and antithyroid antibodies are common. Erectile dysfunction is frequent and may be a presenting manifestation of the disease in men. Pathologic examination shows extensive proliferative/obliterative changes in the penile blood vessels.⁴⁴ Fibrosis of the salivary and lacrimal glands in the absence of inflammation can occur and may be associated with Sjögren's syndrome. Synovial biopsies show fibrosis and characteristic vascular changes in the small arterioles.⁴⁵

ANIMAL MODELS OF SCLERODERMA

Animal models of human disease are indispensable research tools to facilitate the understanding of complex disease states. Such models are used to identify the cellular and molecular components of pathologic process, discover potential therapeutic targets, and develop and evaluate novel treatment strategies. A large number of putative SSc models have been reported, but to date none fully reproduce each of the four cardinal features of the disease: obliterative and proliferative microangiopathy, autoimmunity, inflammation, and fibrosis.⁴⁶ However, as illustrated in [Figure 83-6](#), particular animal models recapitulate selected disease features. Broadly speaking, current mouse models can be divided into four types: (1) naturally occurring disease models, in which spontaneous mutations are associated with a genetically transmitted scleroderma-like phenotype such as tight skin (*Tsk1/+* mouse); (2) induced models in which the scleroderma phenotype is elicited by chemical exposures or by manipulation of the immune system (bleomycin-induced skin and lung fibrosis); (3) transplantation of HLA-mismatched bone marrow cells resulting in chronic sclerodermatous graft-versus-host disease; and (4) genetic manipulations giving rise to engineered mouse strains with heritable scleroderma-like traits.

Figure 83-5 Histologic appearance of scleroderma renal crisis. Characteristic histologic findings include interstitial fibrosis (**A**) and occlusion of intrarenal arteries with neointima formation, fibrinoid necrosis of the vessel wall, and reduplication of the internal elastic lamina (**B**). The glomeruli are shrunken and lack inflammatory cells or proliferative changes (**C**). Intravascular thrombosis resembling the changes of thrombotic thrombocytopenic purpura may be present (**D**).

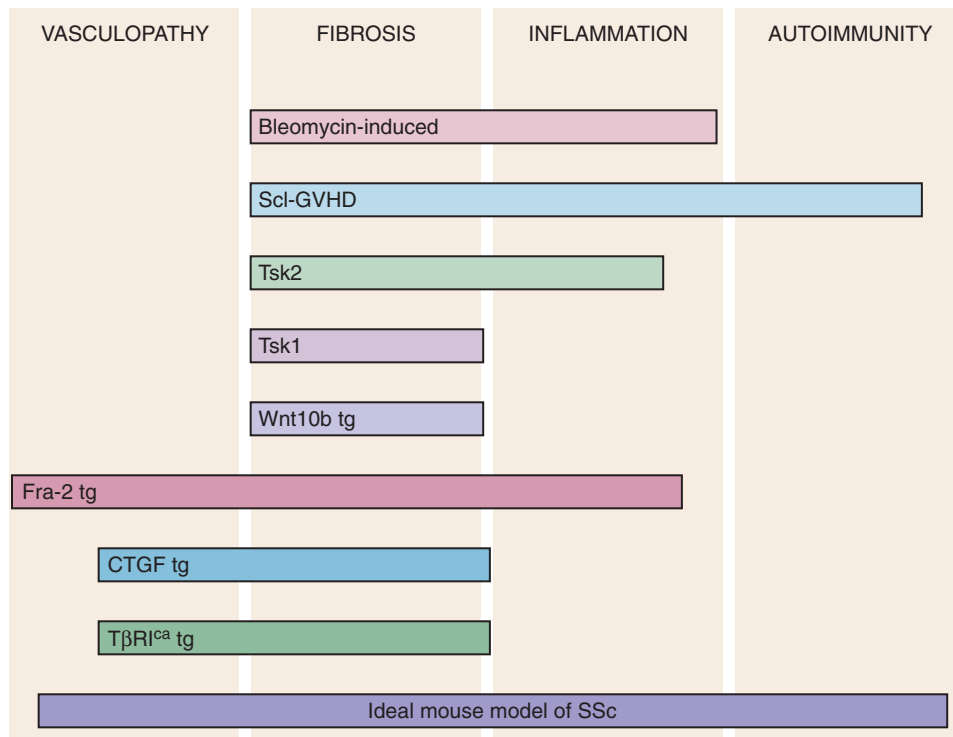

Figure 83-6 Animal models of systemic sclerosis. Mouse models recapitulate selected pathophysiologic features of systemic sclerosis (SSc). Shown are the principal disease processes of SSc (inflammation, autoimmunity, microangiopathy, and fibrosis) and the extent to which they are represented in commonly used mouse models. CTGF, connective tissue growth factor; GVHD, graft-versus-host disease; tg, transgenic. (Modified from Distler JH, Distler O, Beyer C, Schett G: Animal models of systemic sclerosis: prospects and limitations, *Arthritis Rheum* 62(10):2831–2844, 2010.)

Heritable Animal Models of Scleroderma

The Tsk1/+ mouse is characterized by diffuse skin thickening and tethering to the underlying subcutaneous tissue. Mice homozygous for the Tsk1 mutation die in utero at 8 to 10 days of gestation. However, heterozygous mice (Tsk1/+) survive and develop tight skin. In contrast to SSc, Tsk1/+ mice show prominent subcutaneous hyperplasia but relatively unremarkable dermis.⁴⁷ Furthermore, the lungs of Tsk1/+ mice show emphysematous changes rather than fibrosis, and microangiopathy has not been reported. Although inflammation is uncommon, Tsk1/+ mice develop autoantibodies directed against topoisomerase-I. The Tsk1 mutation is now known to be an intragenic tandem duplication fibrillin-1 gene.⁴⁸ Fibrillin-1 is a large ECM protein that is widely distributed in microfibrils, and in addition to its structural role also modulates the latency and activation of TGF- β .⁴⁹ Fibrillin-1 gene mutations are associated with Marfan's disease with multiple tissues showing activation of TGF- β . The fibrillin-1 duplication mutation in Tsk1/+ mice gives rise to an abnormally large 450-kD protein. No corresponding fibrillin-1 mutations have been demonstrated in

patients with SSc. Although it has been hypothesized that accumulation of the abnormally large mutant fibrillin-1 destabilizes the matrix⁵⁰ or perturbs the homeostatic control of TGF- β latency, the precise mechanisms linking the Tsk1/+ mutation in fibrillin-1 to the development of cutaneous hyperplasia are unknown.

Another animal model of scleroderma is the Tsk2 mouse that spontaneously develops scleroderma-like skin changes by 3 to 4 weeks of age.⁵¹ In contrast to Tsk1/+ mice, Tsk2/+ mice have fibrotic dermis with extensive infiltration with mononuclear inflammatory cells and show evidence of autoimmunity. The Tsk2 mutation, originally induced in normal mice by exposure to ethylnitrosourea, is located on chromosome 1 and is inherited as an autosomal dominant trait, although the underlying molecular defect has not yet been identified.

Inducible Animal Models of Scleroderma

Chronic skin and lung fibrosis (Figure 83-7) can be induced in BALB/c or C57 mice by subcutaneous injections of bleomycin or oxidative agents. Bleomycin is an antitumor

Figure 83-7 Bleomycin-induced mouse model of systemic sclerosis. Mice received subcutaneous injection of PBS (**A1**, **A3**) or bleomycin (**A2**, **A4**) for 28 days. **A1-A4**, Skin changes. **A1** and **A2**, H&E stain; **A3** and **A4**, Sirius red stain. Note dermal fibrosis and loss of subcutaneous adipose layer (**A2**), and increased collagen accumulation (**A4**).

chemotherapy drug that has long been recognized to be complicated by pulmonary fibrosis. The sequence of bleomycin-induced histopathologic changes in mice closely resembles those seen in SSc: early and self-limited mononuclear cell infiltration and increased expression of cytokines such as TGF- β , IL-4, IL-6, IL-13, and monocyte chemoattractant protein-1 (MCP-1), followed by the appearance of dermal fibrosis with excessive collagen deposition and accumulation of α -smooth muscle actin-positive

myofibroblasts.⁵² Bleomycin-induced fibrosis may be linked to reactive oxygen species (ROS) generation, as well as direct activation of innate immunity via TLR2. In contrast to SSc, bleomycin-induced mouse scleroderma is not associated with either microangiopathic changes or autoantibodies and skin fibrosis is limited in extent and duration. Nevertheless, in light of its reproducibility, relative strain independence, and ease of induction, this mouse model is widely used for investigating specific molecules and

pathways in the development and treatment of fibrosis. Injection of oxidative agents (such as hydroxyl radicals or hypochlorite) into the skin in BALB/c mice induces skin and lung fibrosis, as well as the appearance of SSc-specific autoantibodies.⁵³ The pathologic changes are linked to the generation of hydrogen peroxide and other ROS. Subcutaneous injection of TGF- β induces granulation tissue and only transient fibrosis, but simultaneous injection of CTGF along with TGF- β results in persistent fibrosis, suggesting that CTGF is required for sustaining the fibrotic response. However, adenovirus-mediated delivery of constitutively active TGF- β receptor I is sufficient to induce local dermal fibrosis. Transplantation of bone marrow or spleen cells into sublethally irradiated minor histocompatibility locus-mismatched recipient mice results in sclerodermatous graft-versus-host disease. This mouse model displays interstitial and perivascular fibrosis in the skin and lung and autoimmunity.⁵⁴ Skin fibrosis is preceded by mononuclear cell infiltration with elevated TGF- β and chemokine expression.

Genetic Manipulations in Mice Giving Rise to Scleroderma-like Phenotypes

Mouse strains with genetic gain-of-function or loss-of-function modifications resulting in spontaneous scleroderma-like phenotypes have been created. These transgenic, knockin, and knockout mice provide robust novel experimental tools in scleroderma research. Mouse strains with constitutive or inducible expression of TGF- β signaling in fibroblasts recapitulate key clinical, histologic, and biochemical features of SSc and provide support for the role of perturbed TGF- β signaling in pathogenesis.^{55,56} Other promising transgenic models of SSc include mice overexpressing CTGF, PDGF receptor (PDGFR)- α , Wnt10b, and Fra-2 and mice null for caveolin-1, relaxin, Fli-1, and fetuin A.⁵⁷ Scleroderma-like fibrotic, vascular, and calcific changes in the skin, as well as in some cases the lungs, develop spontaneously in these mice. Other genetically engineered mice show increased sensitivity to the induction of fibrosis. Examples include *T-bet* null and VEGF null mice. These emerging mouse models provide new exciting research opportunities for the discovery of molecules and pathways underlying the pathogenetic features of SSc.

PATHOGENESIS

Integrated Overview

The pathogenesis of SSc is complex, and existing animal models capture only some of its diverse pathologic and clinical attributes. An integrated view of pathogenesis must integrate the cardinal features of SSc: vascular injury and damage, inflammation with activation of the innate and adaptive arms of the immune system, and fibroblast activation resulting in generalized interstitial and vascular fibrosis. Although evidence for each can be found in each SSc patient, the relative individual contribution of these processes to the clinical manifestations varies from one patient to another. As illustrated in Figure 83-1, complex and dynamic interplay between these distinct processes is thought to be responsible for initiating, amplifying, and sustaining tissue damage in SSc.⁵⁸

Vasculopathy

Vascular injury is likely to be the initiating and proximal event in SSc (see Figure 83-5). Evidence of vascular involvement is early and widespread, and its progression over time is associated with significant clinical sequelae. The presence of nailfold microvascular changes, detected by capillaroscopy, in an individual with isolated Raynaud phenomenon identifies an elevated risk of progression to SSc, indicating that microvasculopathy precedes other clinical manifestations of the disease.

Vascular Injury and the Activated Endothelium

The initial vascular insult is triggered by circulating factors such as (unidentified) cytotoxic molecules or T cell-derived proteolytic granzymes.⁵⁹ Other potential causes of vascular injury include antiendothelial cell autoantibodies, vasculotropic viruses, inflammatory cytokines, ROS, and other forms of environmental stress. Vascular injury causes endothelial cell activation, with increased expression of vascular endothelial cell adhesion molecule-1 and E-selectin, altered secretion of vasoactive mediators, platelet activation, and activation of the thrombotic and fibrinolytic cascades.⁶⁰ In the injured arterioles and capillaries, activated endothelial cells may undergo transdifferentiation to mesenchymal cells via a process termed *endothelial-mesenchymal transition*. This process driven by TGF- β and Notch is associated with loss of endothelial markers such as CD31 and progressive acquisition of mesenchymal markers such as α -smooth muscle actin. Although endothelial-mesenchymal transition has been documented in cancer, recent studies identify endothelial cell-derived fibroblasts in cardiac and pulmonary fibrosis, suggesting that this form of endothelial cell plasticity may also play a role in SSc. Platelet activation is a prominent early feature of vascular injury in SSc and is associated with the release of thromboxane A₂, PDGF, and TGF- β , which potentiate vasoconstriction and also contribute to fibroblast activation and myofibroblast transdifferentiation. Pericytes, which are smooth muscle-like structural cells found in the walls of small blood vessels, show marked hyperplasia in lesional skin from patients with early-stage SSc and express the surface marker Thy-1 (CD90) and receptors for PDGF.^{61,62}

Functional abnormalities of the vascular endothelium include impaired production of and responsiveness to endothelium-derived vasodilatory factors such as nitric oxide (NO), thrombomodulin, calcitonin gene-related peptide, and prostacyclins. The ensuing imbalance of vasodilators and vasoconstrictors impairs blood flow responses. Recurrent episodes of ischemia-reperfusion create oxidative stress with the generation of H₂O₂ and other ROS. Damaged microvessels show increased vascular permeability and enhanced transendothelial leukocyte migration. Platelets are exposed to subendothelial structures, which further aggravates platelet aggregation. Activated endothelial cells release the extremely potent vasoconstrictor ET-1, which promotes leukocyte adhesion, vascular smooth muscle cell proliferation, and fibroblast activation (Figure 83-8). Levels of ET-1 are elevated in the blood and in bronchoalveolar lavage fluids from patients with SSc.⁶³ Ultimately

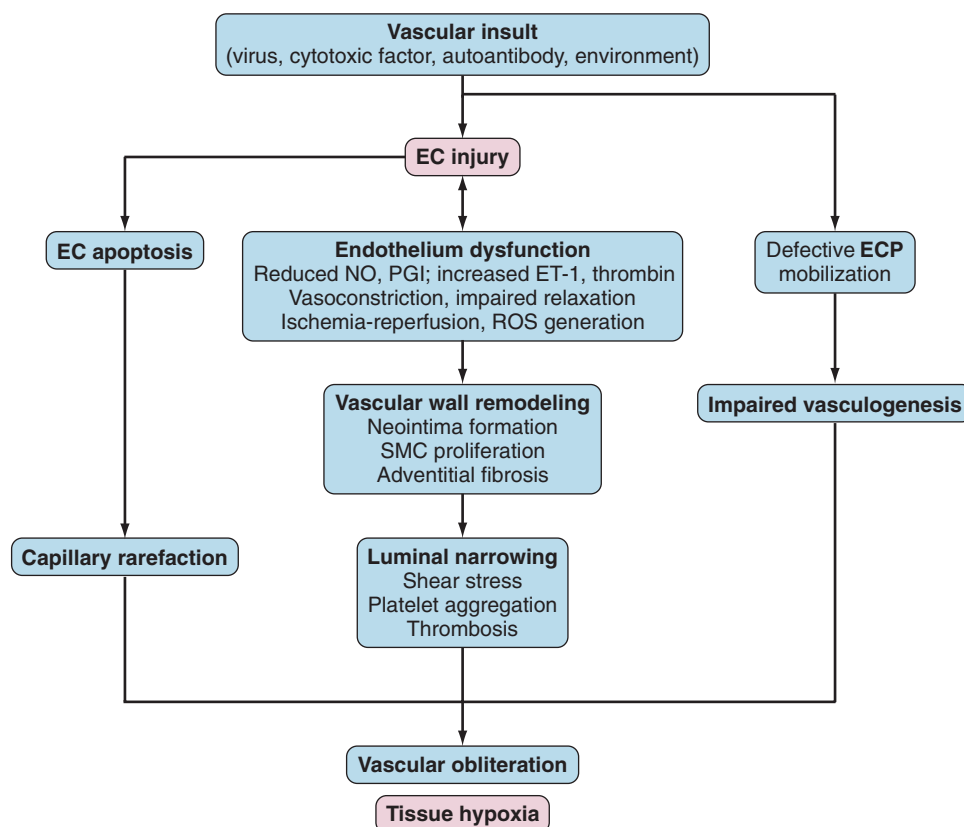

Figure 83-8 Pathogenesis of vasculopathy. Initial vascular insult results in endothelial cell (EC) injury and activation, with reversible functional changes, increased expression of adhesion molecules, and enhanced leukocyte diapedesis resulting in perivascular inflammation. Damaged endothelium promotes platelet aggregation and thrombin release and shows impaired production of vasodilators such as nitric oxide (NO), increased production of vasoconstrictors such as endothelin-1 (ET-1), and release of reactive oxygen species (ROS). Consequent vasoconstriction and defective vasodilation aggravate vascular damage, leading to irreversible and progressive vascular wall remodeling, luminal occlusion, platelet aggregation, in situ thrombosis, and tissue hypoxia. Loss of blood vessels may be further compounded by insufficient vasculogenesis. ECP, endothelial cell progenitor; PGI, prostaglandin I; SMC, smooth muscle cell.

fibrinolytic and coagulation cascades are activated, culminating in intravascular fibrin deposition and thrombosis.

Vascular Damage and Vasculogenesis

In the medium-sized and larger vessels a combination of hypertrophy of the intimal and medial layers and adventitial fibrosis causes progressive luminal narrowing. Together with endothelial cell apoptosis, the process culminates in obliterative vasculopathy and vascular rarefaction, with the characteristic striking decrease of blood vessels seen angiographically in late-stage SSc. Loss of microvasculature results in reduced blood flow and chronic tissue hypoxia, which induces hypoxia-inducible factor-1 (HIF-1) α -dependent genes such as VEGF and its receptors. There is substantial controversy regarding the balance of proangiogenic and antiangiogenic factors in SSc. In some studies, the plasma levels of the angiogenesis inhibitor endostatin, a degradation product of type XVIII collagen, were reported to be increased.⁶⁴ Other studies, however, found elevated levels of the proangiogenic factors VEGF, fibroblast growth factor, and PDGF. Furthermore, the expression of VEGF and its receptors was also elevated in lesional tissue.^{65,66} It is currently unclear why, in the face of tissue hypoxia and elevated angiogenic factors, SSc is associated with progressive loss of blood vessels. Recent studies implicate defective

vasculogenesis as a potential explanation. A reduction in the number of bone marrow-derived circulating endothelial progenitor cells and their impaired differentiation into mature endothelial cells has been described in SSc patients.⁶⁷⁻⁶⁹ Because CD34⁺ circulating endothelial progenitor cells are required for physiologic vasculogenesis in ischemic tissues, defective progenitor cell mobilization or function compromises the vascular repair. Whether the reduction in circulating endothelial progenitor cells in SSc is due to “exhaustion” of the bone marrow, destruction in the peripheral circulation or some other process, remains unresolved.

Hypoxia

The widespread microangiopathy and resultant capillary loss in affected tissues leads to decreased blood flow and consequent hypoxia. With the onset of fibrosis, excessive ECM accumulation increases diffusion distance from blood vessels to cells, further aggravating tissue hypoxia.⁷⁰ Hypoxia is a potent inducer of the basic helix-loop-helix transcription factors HIF-1 α and HIF-1 β . Under normoxic conditions, cellular HIF-1 α is undetectable due to its rapid and efficient proteasomal degradation mediated by the tumor suppressor von Hippel-Lindau (vHL) protein. Because in hypoxic cells pVHL is unable to bind to its target, HIF-1 α

is protected from degradation and translocates into the nucleus, binds to hypoxia-responsive DNA regulatory sequences, and induces the transcription of hypoxia-regulated genes involved in erythropoiesis, angiogenesis, and glucose metabolism. Hypoxia is also a potent *in vitro* and *in vivo* stimulus for ECM remodeling genes such as collagens, prolyl hydroxylases, and lysyl oxidase and promotes epithelial cell differentiation into activated myofibroblasts.^{71,72} These and other hypoxia-induced profibrogenic responses are partially mediated by autocrine TGF- β . A recent paper provides compelling experimental support for the role of hypoxia in exacerbating fibrosis.⁷³ In this study, mice with myeloid-cell-specific deletion of VEGF showed markedly increased tissue hypoxia and activated Wnt- β -catenin signaling upon bleomycin-induced lung injury, culminating in striking exacerbation of fibrosis.

The presence of severe tissue hypoxia in SSc has been documented noninvasively, and oxygen levels in the skin were shown to inversely correlate with skin thickness. In another study using a needle electrode inserted into the dermis, SSc patients exhibited significantly reduced levels of PO₂ (23.7 mm Hg vs. 33.6 mm Hg in controls). Interestingly, HIF-1 α in the lesional skin was undetectable, rather than elevated, as is the case with the hypoxia-inducible VEGF.

Oxidative Stress and Reactive Oxygen Species

Oxidative stress and elevated levels of ROS are implicated in the pathogenesis of SSc.⁷⁴ ROS might be generated from the endothelium in response to repeated episodes of ischemia reperfusion. Normal fibroblasts exposed to TGF- β or to stimulatory PDGFR autoantibodies generate ROS, whereas explanted SSc skin fibroblasts spontaneously produce excessive amounts of ROS via the membrane NADPH oxidase Nox4.⁷⁵ Hydrogen peroxide and other oxygen free radicals in turn stimulate collagen synthesis, TGF- β secretion, and other fibrotic responses in fibroblasts. A role for ROS in pathogenesis is further supported by a

mouse model of scleroderma induced by subcutaneous injections of peroxynitrite or hypochlorite.⁵³

IMMUNE DYSREGULATION

Introduction

A resurgence of interest in understanding the role of immune dysregulation in the pathogenesis of SSc is occurring. Both the innate and adaptive arms of the immune system are activated in early SSc, and autoimmunity manifested by highly specific and mutually exclusive autoantibodies is prominent throughout the course of the disease. Lesional tissues show prominent perivascular accumulation of mononuclear inflammatory cells, whereas circulating leukocytes (including T cells, B cells, monocytes, and dendritic cells) show evidence of activation and polarization and display the “type I interferon signature” associated with SLE and other autoimmune diseases (Figure 83-9). The strong genetic associations between SSc and HLA Class II locus polymorphisms provide support for the immunologic basis of SSc. Nevertheless, whether immune dysregulation is a primary or significant factor in SSc pathogenesis still remains to be established. Current clinical trials are evaluating the efficacy of myeloablative therapy followed by hematopoietic reconstitution as a therapeutic strategy to “reset the immune system” in SSc.

Cellular Effectors of Immune Dysregulation in Scleroderma: T Cells, B Cells, and Monocytes/Macrophages

T Cell Activation

Activation of T cells is evident in lesional tissues, as well as in peripheral blood, and appears to play a direct role in tissue injury. In early SSc, activated CD4 and CD8 T lymphocytes and monocytes/macrophages, and less commonly B cells, eosinophils, mast cells and NK cells, are observed

Figure 83-9 Complex immune dysregulation in scleroderma. An inciting event such as infection, oxidative damage, necrotic/apoptotic cell debris, or environmental toxins causes activation of dendritic cells, possibly via Toll-like receptors (TLRs). Activated dendritic cells produce type I interferon (IFN), which causes Th2 T cell polarization, monocyte differentiation to an alternately activated (M2) phenotype, and B cell activation with plasma cell maturation and production of autoantibodies. Autoantibodies form immune complexes that in turn further induce type I IFN production via TLR signaling. Th2-polarized T cells and M2 macrophages secrete profibrotic chemokines and cytokines, inducing fibroblast activation. Additional T cell subsets such as Tregs and Th17 may also be involved. DAMPs, damage-associated molecular patterns; IL, interleukin; ROS, reactive oxygen species; TGF- β , transforming growth factor- β .

in perivascular regions in the lesional skin, lungs, and other affected organs; these inflammatory cell infiltrates are detectable before the appearance of fibrosis.⁷⁶ In situ hybridization studies show prominent procollagen gene expression in early-stage SSc skin in fibroblasts that are adjacent to inflammatory cells, suggesting a role for the inflammatory cells or their soluble products in inducing fibroblast activation.⁷⁷ The extent of lymphocytic tissue infiltration correlates with the severity and progression of skin fibrosis.

Tissue-infiltrating T cells are predominantly CD3⁺ and CD4⁺ and express activation markers CD69, CD45, HLA-DR, and the IL-2 receptor. These T cells display restricted T cell receptor signatures indicative of oligoclonal T cell expansion in response to an as-yet unidentified antigen.⁷⁸ In the lungs, a predominance of CD8⁺ and γ/δ T cells is observed.⁷⁹ It is not known whether T cells in lesional tissue are activated nonspecifically (by cytokines or chemokines) or specifically in response to an antigen. Evidence of T cell activation in SSc is also detected in the peripheral blood, with elevated serum levels of IL-2 and IL-2 receptor expression, and spontaneous cytokine secretion. Peripheral blood lymphocytes show the “IFN signature” defined by the upregulation of type I IFN-inducible genes.⁸⁰⁻⁸² Increased expression of LFA-1 and α 1 integrins may enable T cells to adhere directly to endothelium and fibroblasts. Circulating CD4⁺ T cells also express elevated chemokine receptors. At the same time, vascular endothelial cells express ICAM-1, E-selectin, and other adhesion molecules that facilitate leukocyte diapedesis.

Th1/Th2 Cytokine Balance and Polarized Immune Responses

Evidence implicates an altered balance between T helper (Th)1 and Th2 cytokines in fibrosis. T cells polarized to a Th2 pattern secrete abundant IL-4, IL-5, and IL-13, with only low levels of the hallmark Th1 cytokine IFN- γ . The Th2 cytokines are considered to be profibrogenic because they can directly stimulate collagen synthesis and myofibroblast transdifferentiation, as well as induce TGF- β , a powerful modulator of immune regulation and ECM accumulation. In contrast, IFN- γ blocks these responses and exerts antifibrotic effects. Thus skewing of the immune response toward a Th2 pattern could create a profibrotic environment.

Animal studies support the significance of a Th2-polarized immune response in fibrosis. For example, T cells that have been Th2 polarized in vitro induce fibrosis when passively transferred in mice. Moreover, mice lacking the transcription factor T-bet, which directs T cell differentiation of T cells toward a Th1-predominant phenotype, spontaneously show a Th2-polarized immune response and develop exaggerated skin fibrosis in response to bleomycin.^{83,84}

Patients with SSc display an altered Th1/Th2 cytokine balance with a predominant Th2 profile. For example, both the serum levels of IFN- γ and in vitro IFN- γ production by peripheral blood monocytes are reduced. Microarray analysis of SSc peripheral blood leukocytes showed elevated expression of GATA3, a transcription factor controlling Th2 polarization. Cloned CD4⁺ T cells from SSc skin biopsies secrete IL-4 but not IFN- γ .⁸⁵ T cell lines generated from SSc skin biopsies show prominent CD8 expression and produce high levels of IL-4. Similarly, alveolar CD8⁺ T cells

show elevated Th2 cytokine production, and the Th2 predominance predicts accelerated decline in lung function.⁸⁶ By analyzing the ratio of chemokine receptors associated with Th1 versus Th2 responses, peripheral blood T cells in SSc were shown to have a Th2-predominant pattern that predicted the presence and progression of interstitial lung disease.⁸⁷ Proteomic and DNA microarray analysis demonstrated a Th2 cytokine predominance in SSc bronchoalveolar lavage fluids and CD8⁺ lymphocytes. A longitudinal study of SSc patients showed that skin improvement over time was associated with a decline in serum levels of Th2 cytokines and a concomitant increase in IL-12, a Th1 cytokine.⁸⁸

Other T Cell Subsets

The Th17 subset of T lymphocytes is implicated in the pathogenesis of rheumatoid arthritis and other inflammatory diseases. SSc patients have increased numbers of IL-17 producing CD4⁺ T cells in both the peripheral blood and bronchoalveolar lavage fluid.⁸⁹ Patterns of Th1, Th2, and Th17 predominant immune responses might be useful in identifying specific clinical phenotypes in SSc.

Suppressor regulatory T cells (Tregs) are important in controlling autoimmunity. Interestingly, although the frequency of peripheral blood Treg cells was increased in SSc patients, they showed impaired suppressive activity and secretion of TGF- β and IL-10.⁹⁰ Other studies failed to replicate these findings but demonstrated reduced numbers of Foxp3⁺ CD4⁺ T cells in the lesional skin compared with other inflammatory skin diseases.

Monocytes and Macrophages

Phagocytic monocytes and macrophages regulate innate immunity and tissue repair. Monocytes are a major source of cytokines and chemokines including IL-1, tumor necrosis factor (TNF), MCP-1, PDGF, and TGF- β , all of which are important in inflammatory and fibroproliferative responses. In addition, monocytes produce collagenases and other matrix-degrading enzymes that mediate tissue remodeling. Macrophages are prominent among the mononuclear cells infiltrating the lesional skin in early SSc and express Siglec-1 and AIF-1, markers of IFN-induced activation. Macrophages exhibit discrete phenotypes in response to specific stimuli, with alternatively activated (M2) macrophages induced in response to IL-4 and TGF- β secreting profibrotic mediators. M2 macrophages accumulate in various organs in animal models of fibrosis, and may be important in pathogenesis. In SSc patients with active lung disease, alveolar macrophages show an M2 phenotype characterized by secretion of profibrotic mediators TGF- β , PDGF, and IL-13. Evidence of local mast cell and eosinophil activation and degranulation is sometimes prominent in lesional skin.

Dendritic Cells

These potent antigen-presenting cells found in the skin and circulation bridge innate and adaptive immunity, and by modulating T cell, B cell, and monocyte/macrophage function shape the immune response (see Figure 83-9).

Dendritic cells are the major source of type I IFN and can also secrete fibrogenic cytokines including TGF- β . Recent studies show that CD11c⁺ dendritic cells accumulate in fibrotic tissue in animal models and in patients with SSc. Activated dendritic cells in the lesional tissue might directly or indirectly modulate resident fibroblast activation. Moreover, monocyte-derived dendritic cells from the peripheral blood in SSc show altered in vitro responses to TLR2/3 ligands and increased secretion of IL-6 and IL-10, which favors a Th2 skewing of the immune response.⁹¹

AUTOIMMUNITY

Autoantibodies in Scleroderma: Pathogenetic Considerations

Humoral autoimmunity, manifested by the presence of autoantibodies with multiple antigenic specificities, can be detected in the serum in virtually all patients. The presence of SSc autoantibodies has significant utility in diagnosis and classification, as well as in predicting organ-specific complications and clinical course. In contrast, a direct role of autoantibodies in tissue damage has not been conclusively established. Autoantibodies in SSc tend to be highly specific and mutually exclusive, and they show strong association with individual disease phenotypes and immunogenetic backgrounds. The levels of autoantibodies, particularly anti-topoisomerase I, may correlate with the extent of skin and lung fibrosis and fluctuate with disease activity.

Various hypotheses exist to explain the generation of autoantibodies in SSc. According to one hypothesis, self-antigens such as topoisomerase I undergo proteolytic cleavage in the presence of ROS, resulting in exposure of normally cryptic epitopes and break in immune tolerance.⁹² Other potential mechanisms include molecular mimicry as a consequence of viral infection, chronic B cell hyperreactivity, and increased expression or altered subcellular localization of potential autoantigenic peptides. Alternately, SSc autoantibodies might be generated from B cells activated by endogenous TLR7 ligands such as nucleic acid-containing cellular debris.

Several reports describe biologically active autoantibodies directed against ECM components, cell membrane PDGF receptors, fibroblasts, and endothelial cells in SSc patients. Stimulatory autoantibodies can induce target cell activation or apoptosis in vitro.^{93,94} In one study, autoantibodies against the PDGF receptor were detected in each of the SSc patients evaluated in one study and shown to induce ROS generation and multiple signaling cascades in normal skin fibroblasts, resulting in myofibroblast differentiation. It is not yet known whether these autoantibodies precede, or are a consequence of, fibrosis, and their direct pathogenetic role in SSc remains to be established.

B Cells in Scleroderma

Recent studies provide evidence for a potential direct role for B lymphocytes in the pathogenesis of SSc. B cells have multiple immune regulatory functions in addition to the generation of antibodies including antigen presentation, cytokine production, lymphoid organogenesis, and T cell differentiation. Although B cells are not generally

prominent in microscopic sections of lesional tissue, DNA microarray analyses demonstrated a molecular signature indicative of activated B cells with increased expression of immunoglobulin genes in some SSc skin biopsies. B cells were also prominent in SSc lung biopsies.⁹⁵ Patients with SSc display intrinsic abnormalities of B cells, with elevated numbers of naïve B cells, and reduced numbers of plasma cells.⁹⁶ Memory B cells are chronically activated and display increased CD95 and CD86, as well as CD19, a signaling cell surface receptor that regulates intrinsic and antigen receptor-induced B cell responses. Transgenic mice overexpressing CD19 develop spontaneous autoimmunity and high titers of antitopoisomerase I antibodies. Altered B cell function and chronic B cell activation in SSc may not only account for autoantibody production but also contribute to fibrosis because activated B cells secrete IL-6, which directly stimulates fibroblast activation and collagen synthesis. Patients with SSc also have elevated levels of the potent B cell survival factor B cell activating factor belonging to the TNF family (BAFF) in the serum and in lesional skin, as well as increased BAFF receptor expression on B cells. In light of the emerging role of B cells in the pathogenesis of SSc, therapies targeting B cells are under consideration.

Type I Interferon Signature and Innate Immune Signaling: Similarities to Systemic Lupus Erythematosus

Stimulation of dendritic cells and other cell types by ligands of TLR3 results in robust secretion of type I IFN. Accordingly, the presence of IFN or IFN-induced cellular responses suggests TLR-mediated innate immune signaling. Type I IFNs (α and β) are themselves potent modulators of innate immunity. Elevated expression of IFN-regulated genes (the "IFN signature") was first described in SLE patients.⁹⁷ Circulating immune complexes containing antinuclear acid autoantibodies serve as endogenous TLR3 ligands that stimulate type I IFN secretion by dendritic cells and macrophages. Similar to SLE, an IFN signature has been detected in circulating leukocytes from SSc patients. Indeed, a recent study reported that the most highly expressed genes in SSc peripheral blood leukocytes were IFN regulated and similar to those detected in SLE.⁸¹ Moreover, incubation of normal leukocytes with SSc sera induced the secretion of IFN, indicative of TLR3 activation by nucleic acid-containing immune complexes in the serum.⁹⁸ Interestingly, serum levels of IFN are only inconsistently elevated in SSc. These observations identify an important role for TLR-mediated innate immune signaling and type I IFNs in SSc and highlight immunopathogenic similarities between SLE and SSc, but they fail to explain why these two related autoimmune diseases display largely nonoverlapping clinical phenotypes. The direct pathogenetic role of type I IFN in the development of microangiopathy and fibrosis in SSc remains to be established.

FIBROSIS

Overview

Fibrosis, characterized by replacement of normal tissue architecture with stiff paucicellular connective tissue, is

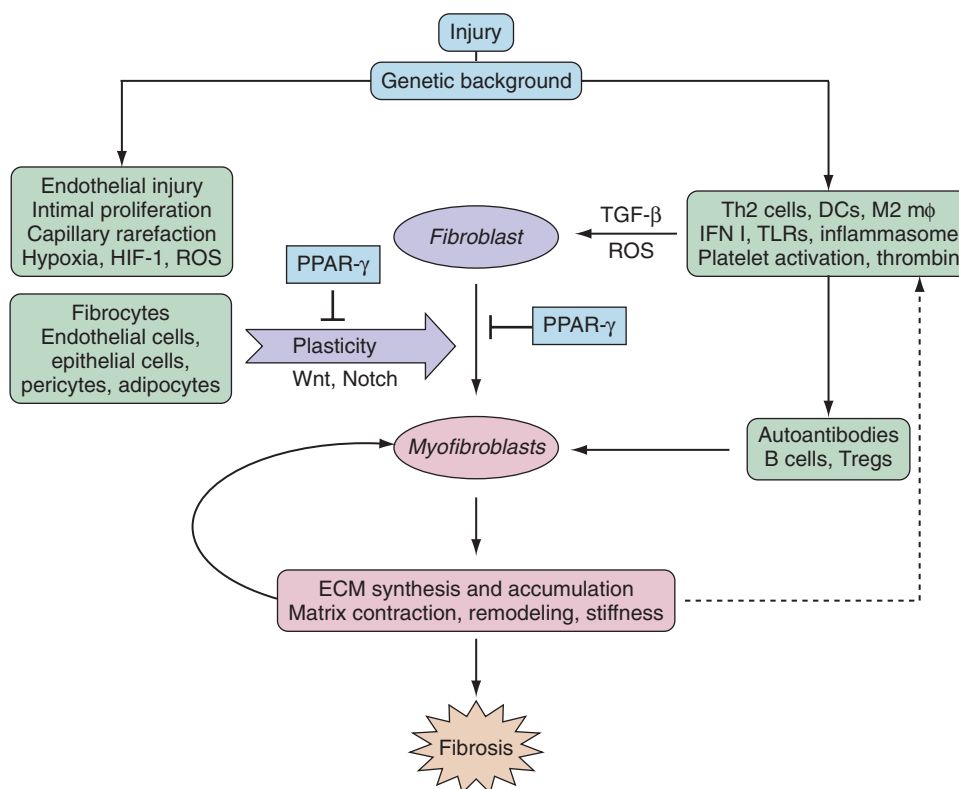

Figure 83-10 Pathogenesis of fibrosis. Fibrosis is the end result of immune dysregulation and vascular damage and hypoxia. Injury causes vascular damage, perivascular inflammation, and innate immune signaling, with oxidative stress, secretion of inflammatory and fibrogenic cytokines and chemokines, autoantibodies, fibroblast activation, and myofibroblast accumulation. Circulating mesenchymal progenitor cells traffic to and accumulate within the lesional tissue and transdifferentiate into fibrotic fibroblasts, accelerating matrix accumulation. Tissue hypoxia, matrix remodeling, and stiffness further contribute to fibroblast activation, which causes disruption of tissue architecture and organ failure. DCs, dendritic cells; ECM, extracellular matrix; HIF-1, hypoxia-inducible factor-1; IFN, interferon; PPAR- γ , peroxisome proliferator-activated receptor- γ ; ROS, reactive oxygen species; TGF- β , transforming growth factor- β ; TLRs, Toll-like receptors.

the pathologic hallmark of SSc and can be viewed as a form of aberrant wound healing. Fibrosis represents the end result of a complex series of vascular and immune-mediated responses to injury in a genetically predisposed individual. As illustrated in [Figure 83-10](#), injured or activated vascular and immune cells produce soluble mediators, autoantibodies, and ROS that induce the activation and differentiation of mesenchymal effector cells, culminating in excessive and ultimately irreversible ECM accumulation and remodeling.

Extracellular Matrix

The ECM consists of a cellular compartment of resident fibroblasts and myofibroblasts and infiltrating cells, as well as connective tissue composed of large structural proteins such as collagens, proteoglycans, fibrillins, and adhesion molecules. The ECM also serves as a reservoir for sequestering growth factors and matricellular proteins that, together with the connective tissue compartment, control the differentiation, function, and survival of mesenchymal cells. Excessive connective tissue accumulation results from overproduction by fibroblasts activated by soluble factors, hypoxia, and ROS; signals from the surrounding ECM; or via cell-cell interactions. Impaired matrix degradation and turnover, as well as expansion of the pool of ECM-producing mesenchymal cells, also play roles.

Regulation of Collagen Synthesis

The family of collagens is composed of more than two dozen structural proteins with critical roles in organ development, growth, and differentiation. The ECM of the skin, bones, and tendons is composed largely of type I collagen, with smaller amounts of associated type III collagen. Type II collagen is found mainly in articular cartilage. The fibrillar collagens consist of three α chains wound into a characteristic triple helix, a structure made possible by the presence of a glycine at every third residue of repeating Gly-X-Y sequence, where X is frequently a proline and Y is frequently a hydroxyproline. During their biosynthesis, fibrillar collagens undergo extensive enzymatic modifications inside the cell and additional processing following their secretion. Covalent cross-linking stabilizes the collagen fiber network in the extracellular space.

Type I collagen synthesis is regulated by cytokines and other soluble extracellular factors, ROS, hypoxia, and cell-cell and cell-matrix contact ([Table 83-3](#)). Environmental cues allow fibroblasts to respond to dynamic tissue requirements during development and tissue repair. The genes encoding the various collagens harbor cis-acting regulatory elements that are specifically recognized by DNA-binding transcription factors. Sp1, Ets1, Smad2/3, Egr-1, and CCAAT-binding factor (CBF) stimulate, and Sp3, C/EBP, YB1, c-Krox, and Fli-1 suppress transcription.⁹⁹ These

Table 83-3 Extracellular Factors Potentially Contributing to the Pathogenesis of Fibrosis in Systemic Sclerosis

Signal	Cellular Source
TGF- β	Inflammatory cells (macrophages, T cells), platelets, fibroblasts
PDGF	Platelets, macrophages, fibroblasts, endothelial cells
CTGF/CCN2	Fibroblasts
IGF-1	Fibroblasts
IL-1 α	Keratinocytes
IL-4, IL-13	Th2 lymphocytes, mast cells
IL-6	Macrophages, B cells, T cells, fibroblasts
Chemokines (MCP-1, MCP-3)	Neutrophils, epithelial cells, endothelial cells, fibroblasts
Fibroblast growth factor	Fibroblasts
ET-1	Endothelial cells
Wnt ligands	Developmental pathway aberrantly reactivated
Notch/Jagged	Developmental pathway aberrantly reactivated
Hypoxia	Hypoxic underperfused tissue
ROS	Generated from ischemia reperfusion

CTGF, connective tissue growth factor; ET-1, endothelin-1; IGF-1, insulin-like growth factor-1; IL, interleukin; MCP, monocyte chemotactic protein; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; SSc, systemic sclerosis; TGF- β , transforming growth factor- β .

transcription factors interact with one another and with non-DNA-binding cofactors, scaffold proteins, and chromatin-modifying enzymes such as p300/CBP, PCAF, and histone deacetylases. The activities and interactions of transcription factors and cofactors are controlled by extracellular cues. Enzymes that modify chromatin structure, causing it to unwind, enhance DNA-binding factor access to cognate cis-acting regulatory sequences and facilitate transcription.¹⁰⁰ Alterations in the levels, activities, or interactions among the various transcription factors, co-factors, and chromatin-modifying enzymes contribute to persistent fibroblast activation in SSc.

Effector Cells of Fibrosis: Fibroblasts

Fibroblasts are versatile spindle-shaped cells that are capable of both synthesis and degradation of ECM. Although unstimulated fibroblasts are biosynthetically quiescent, under the influence of appropriate extracellular signals they secrete ECM macromolecules and growth factors, cytokines and growth factors; adhere to and contract connective tissue; and transdifferentiate into myofibroblasts. Together, these biosynthetic, proinflammatory, contractile, and adhesive functions enable fibroblasts to execute effective wound healing. Whereas under physiologic conditions the fibroblast repair program is self-limited, pathologic fibrosis is characterized by uncontrolled fibroblast activation that results in exaggerated ECM accumulation and remodeling.¹⁰¹ Recent DNA microarray studies reveal that fibroblasts explanted from different anatomic locations differ markedly in their pattern of gene expression, suggesting that fibroblasts in different sites in the body could be considered distinct differentiated cell types.¹⁰² The apparent “positional memory” of fibroblasts is governed by genetic imprinting by the homeobox (HOX) family transcription factors.

Effector Cells of Fibrosis: Myofibroblasts, Pericytes, Endothelial Cells, and Cellular Plasticity

In fibrosis, the tissue pool of activated mesenchymal cells is expanded by not only proliferation of resident fibroblasts but also transdifferentiation of other cell types, as well as the influx of bone marrow–derived mesenchymal progenitor cells. Myofibroblasts characterized by the cytoskeletal protein α -smooth muscle actin are specialized cells that arise from resident fibroblasts, as well as epithelial and endothelial cells and fibrocytes in response to TGF- β . Myofibroblasts synthesize collagens, tissue inhibitor of metalloproteinases (TIMPs), and other ECM components and are a major source of TGF- β during the fibrotic response. During normal wound healing, myofibroblasts are detected transiently in the early granulation tissue and then disappear via apoptosis. The removal of fibroblasts is a crucial step in wound resolution. In pathologic fibrogenesis myofibroblasts persist in lesional tissue, resulting in excessively contracted ECM that is characteristic of chronic scar.

Pericytes are mesenchymal cells in the walls of small blood vessels that are normally in intimate contact with the underlying endothelium and regulate vascular homeostasis. In SSc patients, a marked increase in microvascular pericyte compartment and increased expression of PDGF receptors has been reported. Activated pericytes can transdifferentiate into collagen-producing fibroblasts and myofibroblasts, thus linking microvascular injury and fibrosis.

Under certain conditions, epithelial cells can also undergo transformation to fibroblasts. Epithelial-mesenchymal transition (EMT) plays a vital role during vertebrate embryonic development. On stimulation, epithelial cells lose characteristic markers and cell-cell adhesion and acquire fibroblast markers such as α -smooth muscle actin. Pathologic EMT occurs prominently in cancer and is increasingly implicated in renal fibrosis and idiopathic pulmonary fibrosis.¹⁰³ Similar to epithelial cells, vascular endothelial cells can, on injury, undergo a transition to fibroblasts. This process, called *EndMT*, has been demonstrated in various forms of experimentally induced fibrosis. Both EMT and EndMT are stimulated by TGF- β and Notch, and both processes might be implicated in tissue fibrosis in SSc.

Fibrocytes and Monocyte-Derived Mesenchymal Progenitor Cells

Fibrocytes are bone marrow–derived CD34⁺ mesenchymal progenitor cells normally present in small numbers in the peripheral blood that can present antigen and also synthesize collagen.¹⁰⁴ These bone marrow–derived cells express CD14⁺ (a monocyte marker), as well as chemokine receptors (CCR3, CCR5, and CXCR4), which allows them to accumulate in specific tissues. The role for circulating fibrocytes and their trafficking into lesional tissue in the pathogenesis of fibrosis was established in animal models using neutralizing antibodies and in CXCR4-deficient mice. Mice with accelerated senescence have an increased number of circulating fibrocytes and show increased sensitivity to bleomycin-induced fibrosis. It is thought that in lesional tissue, fibrocytes undergo differentiation into activated myofibroblasts, losing the CD14 and CD34 markers in

the process, and contribute to the progression of fibrosis. Other studies have identified multipotent monocyte-derived mesenchymal progenitor cells in peripheral blood. However, the role of fibrocytes and other bone marrow-derived progenitor cells in SSc-associated fibrosis remains speculative.

MOLECULAR DETERMINANTS OF FIBROSIS: TRANSFORMING GROWTH FACTOR- β

The expression of ECM genes is normally tightly regulated by paracrine/autocrine mediators, cell-cell contact, hypoxia, and contact with the surrounding ECM. Multiple cytokines are implicated in SSc (see Table 83-3). Of these, TGF- β is considered to be the master regulator of both physiologic fibrogenesis (wound healing and tissue repair) and pathologic fibrosis. TGF- β plays essential roles in normal tissue repair, angiogenesis, and immune regulation and is implicated in cancer, fibrosis, and autoimmunity. Most cell types secrete TGF- β as a latent complex that is sequestered within the ECM. Under appropriate conditions, latent TGF- β is converted to its biologically active form that is capable of triggering cellular responses. The activation of latent TGF- β is controlled in part by fibrillin-1 and is mediated by integrins, thrombospondins, $\alpha v \beta 6$ integrin, and proteolytic enzymes. Because of its fundamental role in orchestrating fibrotic responses, TGF- β is considered as a potential therapeutic target in SSc. Blocking TGF- β activity via biologic approaches using neutralizing antibodies and blocking intracellular TGF- β signaling using small molecular kinase inhibitors such as the c-Abl blocker imatinib mesylate (Gleevec) are undergoing evaluation. To date, small clinical trials of such interventions have not shown significant efficacy in modifying the course of fibrosis.

Cellular Signaling by Transforming Growth Factor- β : Canonical Smad Pathways

A member of a large cytokine superfamily that also includes activin and bone morphogenetic proteins, TGF- β is secreted by platelets, monocytes/macrophages, dendritic cells, and fibroblasts, and most cell types express surface receptors for TGF- β . The type of response elicited by TGF- β is specific for the target cell lineage and is context dependent. In mesenchymal cells, TGF- β acts as a potent inducer of fibrillar collagen synthesis; stimulates fibroblast proliferation, migration, adhesion, and transdifferentiation into myofibroblasts; and suppresses the production of matrix-degrading metalloproteinases (Table 83-4). In endothelial and epithelial cells, TGF- β drives transdifferentiation into fibroblasts. Activated TGF- β binds to the type II TGF- β receptor, triggering an intracellular signal transduction cascade that leads to the induction of target genes. The evolutionarily conserved canonical TGF- β signal transduction pathway involves phosphorylation of the type I TGF- β receptor, a serine-threonine kinase that in turn phosphorylates cytosolic Smads. Ligand-induced phosphorylation of Smad2/3 allows them to form heterocomplexes with Smad4 and translocate into the nucleus, where they bind to a consensus Smad-binding element (SBE) and recruit

Table 83-4 Fibrogenic Activities of Transforming Growth Factor- β (TGF- β) Relevant to Systemic Sclerosis

Recruits monocytes
Stimulates synthesis of collagens, fibronectin, proteoglycans, elastin, tissue inhibitor of metalloproteinases; inhibits matrix metalloproteinases
Stimulates fibroblast proliferation, chemotaxis
Induces fibrogenic cytokine production: connective tissue growth factor; autoinduction; blocks type II interferon synthesis and activity
Stimulates production of endothelin-1
Stimulates generation of reactive oxygen species
Stimulates expression of surface receptors for TGF- β , PDGF
Induces fibroblast mitogenic responses to PDGF-AA
Promotes fibroblast-myofibroblast differentiation, monocyte-fibrocyte differentiation
Promotes epithelial-mesenchymal transition, endothelial mesenchymal transition
Inhibits fibroblast and myofibroblast apoptosis

PDGF, platelet-derived growth factor.

transcriptional cofactors such as the histone acetylase p300/CBP, resulting in gene transcription. Conserved SBE sequences are found in many TGF- β -inducible genes including type I collagens, PAI-1, α -smooth muscle actin, and CTGF. Ligand-induced signal transduction through the Smad pathway is tightly controlled by endogenous inhibitors such as Smad7 and BAMBI.

Noncanonical Transforming Growth Factor- β Signaling

Although the Smad pathway is the central mediator of signals from the TGF- β receptors, recent evidence indicates the existence of alternative non-Smad pathways. Non-Smad signaling molecules activated by TGF- β include protein kinases (c-Abl, p38 and JNK, integrin-associated focal adhesion kinase FAK, and TGF- β activated kinase TAK1); lipid kinases such as PI3 kinase and its downstream target Akt; and the calcium-dependent phosphatase, calcineurin. Signaling via c-Abl is particularly relevant to SSc because this nonreceptor tyrosine kinase implicated in chronic myelogenous leukemia (CML) mediates profibrotic signals induced by TGF- β and PDGF and is activated in SSc fibroblasts.¹⁰⁵ Imatinib is an effective small molecule inhibitor of c-Abl that is highly effective for the treatment of CML. In scleroderma skin fibroblasts in culture imatinib reversed the abnormal ECM gene expression, and in mouse models of scleroderma, imatinib treatment prevented the development of skin fibrosis.¹⁰⁶

CYTOKINES, GROWTH FACTORS, CHEMOKINES, AND LIPID MEDIATORS

Multiple cytokines, growth factors, chemokines, and eicosanoids that regulate ECM accumulation and mesenchymal cell function show aberrant expression or activity in SSc. Soluble mediators such as CTGF, PDGF, IL-4, IL-6, IL-13, adenosine, prostaglandin F2 α , and lysophosphatidic acid (LPA1) each contribute to the pathogenesis of fibrosis and therefore represent potential therapeutic targets.

Connective Tissue Growth Factor/CCN2

CTGF is a cysteine-rich 40-kD member of the CCN early-response gene family. This matricellular growth factor is implicated in angiogenesis, wound healing, and development. In normal adults, CTGF is undetectable, but its expression is markedly elevated in fibrotic conditions. Serum levels of CTGF correlate with the extent of skin and pulmonary fibrosis in SSc patients. The expression of CTGF can be induced in normal fibroblasts by TGF- β , IL-4, and VEGF, whereas TNF and iloprost block stimulation. Transgenic mice overexpressing CTGF develop scleroderma-like diffuse skin fibrosis and microvascular pathology.¹⁰⁷ In vitro, CTGF exerts multiple profibrotic effects in normal fibroblasts. Because many of these CTGF effects parallel those induced by TGF- β , it has been suggested that TGF- β responses are mediated through endogenous CTGF. The identity of the cellular CTGF receptors and the mechanism of action underlying CTGF profibrotic responses remain incompletely characterized.

Platelet-Derived Growth Factor

PDGFs are disulfide-bonded heterodimeric proteins that act mainly on stromal cells and regulate the wound healing process. Originally isolated from platelets, PDGF isoforms are also secreted from macrophages, endothelial cells, and fibroblasts. PDGF, signaling via the α and β transmembrane receptors, acts as a potent mitogen and chemoattractant for fibroblasts. Moreover, PDGF induces ROS generation and stimulates the synthesis of collagen, fibronectin, and proteoglycans, as well as the secretion of TGF- β 1, MCP-1, and IL-6. Transgenic mice expressing a constitutively active PDGF- α receptor develop progressive fibrosis in the skin and multiple organs.¹⁰⁸ Lesional skin fibroblasts from SSc patients show elevated PDGF and PDGF- β receptor expression,¹⁰⁹ and PDGF levels are increased in the bronchoalveolar lavage fluid. In SSc patients, serum antibodies to the PDGF receptor induce fibroblast activation and ROS generation in vitro; however, these antibodies are not specific for SSc and have also been detected in patients with graft-versus-host disease.

Developmental Pathways: Wnt and Notch

Wnt and Notch developmental pathways required for embryogenesis appear to be deregulated in fibrosis and SSc. The Wnts comprise a family of poorly soluble glycoproteins with dual roles in cell-cell adhesion and transcriptional regulation. Although Wnts have essential roles in morphogenesis, stem cell homeostasis, and cell fate determination, abnormal Wnt signaling is implicated in colorectal cancer, as well as rheumatoid and osteoarthritis, osteoporosis, PAH, and aging. Intracellular Wnt signaling is mediated via canonical (β -catenin) and noncanonical pathways, and there is extensive cross-talk with TGF- β signaling. Transcription of a large number of genes with diverse biologic functions including multiple genes associated with tissue remodeling and pathologic fibrosis are induced by Wnts through β -catenin. Transgenic mice overexpressing Wnt10b or a constitutively-active mutant β -catenin develop

exuberant wound healing, dermal fibrosis, and increased collagen synthesis in the skin.¹¹⁰ Lungs from patients with idiopathic pulmonary fibrosis show increased nuclear β -catenin accumulation at fibrotic foci. Expression profiling analysis of SSc skin biopsies shows elevated expression of Wnt ligands, Wnt receptors, and Wnt targets. Notch is a transmembrane receptor activated by its ligand, Jagged, which has a fundamental role in embryonic development, wound healing, and tissue repair. Notch signaling regulates endothelial cell and fibroblast responses including myofibroblast differentiation. A mouse model of scleroderma showed markedly activated Notch signaling in the skin and lungs, and the activity of ADAM-17, a proteinase induced by TGF- β and ROS that initiates Notch signal transduction, was elevated in SSc skin biopsies.¹¹¹

Interleukins

IL-1 is secreted by multiple cell types. A recent study showed that SSc epidermal keratinocytes are activated and secrete IL-1 α . Co-culture of SSc keratinocytes with normal skin fibroblasts resulted in fibroblast activation and myofibroblast differentiation that was mediated by IL-1 α secreted by keratinocytes. The Th2 cytokine IL-4 stimulates fibroblast proliferation, chemotaxis, collagen synthesis, and production of TGF- β , CTGF, and TIMP. Serum levels of IL-4 are elevated in SSc, and the number of IL-4-producing T lymphocytes is increased in peripheral blood and skin. IL-6, produced by monocytes and T lymphocytes, fibroblasts, and endothelial cells, stimulates collagen and TIMP-1 synthesis and promotes a Th2-polarized immune response. The biologic activities of IL-6 are mediated via the JAK-STAT intracellular signaling pathway shared with other cytokines. Serum levels of IL-6 are elevated in SSc and correlated with the severity of skin involvement. IL-13 is implicated in asthma and other fibrotic conditions. The profibrotic effects of IL-13 involve both indirect mechanisms due to stimulation of TGF- β production by macrophages and direct stimulation of fibroblast proliferation and collagen synthesis. Serum levels of IL-13 are elevated in SSc.

Chemokines

Chemokines represent a superfamily of more than 40 low-molecular-weight soluble mediators originally characterized by their chemotactic effects on leukocytes but now recognized to have a broad range of cellular targets and biologic activities. They play important roles in angiogenesis, wound healing, and fibrosis. The CC chemokine MCP-1 stimulates collagen production directly, as well as through induction of endogenous TGF- β production. Serum levels of MCP-1, along with those of MIP-1 α , IL-8, CXCL8, and CCL18, are elevated in SSc and correlate with the severity of skin fibrosis. Mononuclear cells and dermal fibroblasts from SSc patients spontaneously produce these chemokines, and lesional SSc fibroblasts show constitutive upregulation of the MCP-1 receptor CCR2. Because MCP-1 drives a Th2 response, the MCP-1-CCR2 axis is thought to play a major role in the pathogenesis of SSc by amplifying collagen stimulation and promoting Th2 cytokine production. Significantly, MCP-1 null mice are resistant to the development

of fibrosis induced by bleomycin.¹¹² Enhanced MCP-1 and MCP-3 expression was noted in lesional skin in SSc, particularly in early disease. These chemokines promote transendothelial migration of mononuclear cells in vitro. The levels of MIP-1 α , CXCL8, and CCL18 are also elevated in SSc bronchoalveolar lavage fluid. One study showed that elevated CCL18 levels identified SSc patients who had pulmonary fibrosis, and changes in CCL18 serum levels showed a strong negative correlation with changes in lung function in this cohort. Additional chemokines overexpressed in lesional tissue or serum in patients with SSc or in animal models of scleroderma include RANTES and PARC (CC chemokines), as well as IL-8, MIP-2, and fractalkine (CXC chemokines). The insulin-like growth factor binding protein-1 (IGFBP-1) stimulates collagen synthesis and fibroblast proliferation and induces TGF- β . Patients with SSc have elevated levels of IGF-1 in bronchoalveolar lavage fluids. Expression of IGFBP-3 is markedly elevated in SSc fibroblasts. Adenovirally mediated overexpression of IGFBP-5 resulted in the induction of chronic scleroderma-like fibrosis in mice.¹¹³

Bioactive Lipids

A variety of bioactive lipids are potent modulators of fibroblast function. Although some prostanoids inhibit fibrotic responses through a variety of mechanisms, prostaglandin F (PGF₂ α) was shown to be elevated in patients with pulmonary fibrosis and can stimulate collagen production and fibroblast proliferation.¹¹⁴ Mice with targeted deletion of the PGF receptor are protected from bleomycin-induced pulmonary fibrosis. Lysophosphatidic acid (LPA), generated via the hydrolysis of membrane phospholipids, exerts multiple biologic activities via G protein-coupled transmembrane receptors. Recently LPA was shown to induce fibroblast chemotaxis and CTGF production. The levels of LPA are elevated in the lungs of patients with pulmonary fibrosis. Moreover, LPA1 knockout mice are protected from bleomycin-induced skin and lung fibrosis. A recent study indicates that LPA induces α v β 6 integrin-mediated TGF- β activation in epithelial cells, contributing to sustained autocrine TGF- β signaling.¹¹⁵

Regulation of Fibroblast Function via Innate Immune Signaling: Toll-like Receptors and the Inflammasome

The IFN signature observed in SSc leukocytes and genetic association with mediators of innate immunity support the role of TLR-mediated innate immune responses in SSc. All cell membrane and endosomal TLRs are expressed on normal fibroblasts. Activation of TLR4 by lipopolysaccharide (LPS) plays a critical role in liver fibrosis, with sensitization to TGF- β as the underlying mechanism. In addition, TLR4 also induced the expression of the profibrotic transcription factors Egr-1 and Egr-2. In SSc, fibroblast TLRs might be activated by endogenous TLR ligands called *damage-associated molecular patterns* generated by tissue injury, autoimmunity, and oxidative stress. Endogenous TLR ligands that could play a role in SSc belong to three categories: ECM-derived molecules such as hyaluronan and

its small-molecular-weight degradation products, tenascin C, alternatively spliced extra domain A (EDA) of fibronectin and biglycan; cellular stress proteins such as HMGB1 and Hsp60; and nucleic acids and immune complexes released from damaged or necrotic cells. The expression of both TLR3 and TLR4 is elevated in SSc skin and lung biopsies and is accompanied by substantial increases in hyaluronan, tenascin C, and alternately spliced fibronectin levels. The TLR3 ligand poly(I:C) causes dramatic induction of type I IFN, IL-6, and other inflammatory cytokines, as well as ECM molecules, in normal fibroblasts. These observations suggest that fibroblasts exposed to endogenous TLR ligands during tissue injury switch to an activated phenotype. In this way, fibroblast TLR signaling initiated by damage-associated endogenous TLR ligands in SSc might convert a self-limited regenerative tissue repair into an aberrant and intractable fibrotic scar.

Recently identified innate immune sensors in addition to TLRs include NOD-like receptors (NLRs), RIG-I, and Nalp3. These intracellular receptors respond to cytosolic nucleic acids, damage-associated endogenous molecules, and environmental signals such as silica, bleomycin, and gadolinium. Once activated, these receptors facilitate inflammasome assembly with activation of caspase-1 and secretion of proIL-1 β and IL-18. *NLRP1* is a susceptibility gene for SSc and associated pulmonary fibrosis. Inflammasome activation and IL-1 β play an important role in experimental mouse fibrosis and appear to be important in fibroblast activation of SSc as well.¹¹⁶

Negative Regulation of Extracellular Matrix Accumulation

To prevent excessive matrix accumulation and scarring in response to injury, redundant biologic mechanisms have evolved. Fibroblasts are equipped with endogenous molecules that repress ECM gene expression and TGF- β stimulation. For example, Smad7 is an inhibitory Smad that blocks TGF- β signal transduction by accelerating ubiquitin-mediated TGF- β receptor degradation. Functional impairment of Smad7 was demonstrated in SSc fibroblasts. Other cell-intrinsic endogenous repressors of collagen synthesis include the transcription factors Sp3, Fli-1, p53, Ras, Nrf2, and the nuclear hormone receptor, peroxisome proliferator-activated receptor- γ (PPAR- γ). Impaired expression, induction, or function of these endogenous inhibitors may be responsible for failure to limit fibroblast activation in SSc.

Interferon- γ

IFN- γ , produced primarily by Th1 lymphocytes, is a major negative regulator of collagen gene expression and fibroblast activation. IFN- γ represses collagen gene expression and abrogates stimulation induced by TGF- β .¹¹⁷ IFN- γ is also a potent inhibitor of fibroblast proliferation, fibroblast-mediated matrix contraction, and myofibroblast transdifferentiation. Significantly, some studies have shown that fibroblasts from patients with SSc are relatively resistant to the inhibitory effects of IFN- γ . Clinical trials of IFN- γ in SSc have demonstrated a modest and inconsistent improvement in skin fibrosis.

Peroxisome Proliferator-Activated Receptor- γ

PPAR- γ is an intracellular molecule that modulates TGF- β signaling and mesenchymal cell plasticity and is functionally associated with fibrosis. Originally identified in adipocytes as a key regulator of adipogenesis and lipid metabolism, PPAR- γ is a dual function molecule acting as both a nuclear hormone receptor and ligand-inducible transcription factor. Multiple lipid moieties and electrophilic prostanoids such as 15d-prostaglandin J₂ (15d-PGJ₂) serve as endogenous ligands for PPAR- γ . Insulin-sensitizing drugs such as rosiglitazone and pioglitazone are potent pharmacologic PPAR- γ agonists. PPAR- γ modulates vascular and immune processes, and abnormal PPAR- γ function is implicated in lipodystrophy, atherosclerosis, PAH, and inflammatory diseases. Activation of fibroblasts with 15d-PGJ₂ or pharmacologic PPAR- γ ligands resulted in a virtual abrogation of TGF- β -induced collagen production, myofibroblast transdifferentiation, EMT, and other Smad3-dependent transcriptional responses. The expression and activity of PPAR- γ are impaired in patients with diffuse cutaneous SSc (dcSSc).¹¹⁸ Furthermore, PPAR- γ expression shows an inverse relationship with enhanced TGF- β signaling in lesional tissue. Of note, multiple factors implicated in SSc pathogenesis including TGF- β , Wnt ligands, IL-13, hypoxia, LPA, and CTGF potently inhibit PPAR- γ expression, which might account for impaired PPAR- γ expression in SSc. Together, these findings implicate altered PPAR- γ expression and function in SSc.

SCLERODERMA FIBROBLAST

Fibroblasts explanted from lesional skin or fibrotic lungs of patients with SSc display an abnormal activated phenotype that persists during their serial passage in vitro, indicating autonomous alteration in cell function. The “SSc phenotype” is characterized by the following: enhanced ECM synthesis, secretion of profibrotic cytokines and chemokines, and resistance to IFN- γ and other inhibitory signals. Moreover, SSc fibroblasts show features of myofibroblast transdifferentiation, in part because of constitutive activation of the FAK focal adhesion kinase. It remains unsettled whether the activated SSc fibroblast phenotype represents an intrinsic abnormality or activation in response to exogenous stimuli in the fibrotic milieu.

Numerous molecules of signal transduction and transcriptional regulation have been reported to be abnormally expressed or constitutively activated in SSc fibroblasts. The list includes protein kinase C, Smad3, Egr-1, p300, and c-Abl. Elevated expression of the prosurvival factors Bcl-2 and Akt in SSc fibroblasts may play a role in their relative resistance to apoptosis. Because most of the SSc fibroblast characteristics can be induced in normal fibroblasts by treatment with TGF- β , it has been suggested that the SSc phenotype is due to autocrine TGF- β signaling. The levels of TGF- β receptors are elevated on SSc fibroblasts, which might enable these cells to mount a robust response to endogenously produced TGF- β or to low levels of environmental TGF- β . Furthermore, SSc fibroblasts have elevated levels of thrombospondin and $\alpha v \beta 3$ integrins, which mediate latent TGF- β activation at the cell surface. Consistent with the autocrine TGF- β hypothesis, SSc fibroblasts

show constitutive TGF- β signaling, with elevated Smad3 activation, and constitutive interaction with the histone acetyltransferase p300/CBP. Other studies demonstrate defective expression or function of endogenous suppressors of TGF- β signaling and ECM production, suggesting that failure to terminate fibroblast activation may represent a fundamental defect in SSc. Endogenous molecules that negatively regulate fibroblast activation include Fli-1, PTEN, PPAR- γ , and Smad7. Autocrine TGF- β activation of fibroblasts cannot fully account for all of the phenotypic hallmarks of SSc fibroblasts such as constitutive CTGF production, indicating that both Smad-independent TGF- β signaling mechanisms, as well as non-TGF- β -mediated activation events, are involved in the induction or maintenance of the SSc phenotype. The autonomous SSc phenotype could also result from abnormal integrin-mediated signaling from the surrounding ECM. Moreover, epigenetic alterations in SSc fibroblasts are associated with persistent and heritable fibroblast dysfunction. For example, silencing the *FLI-1* gene, an important endogenous negative regulator of collagen gene expression, by DNA methylation or chromatin histone deacetylation suppresses its expression in fibroblasts from lesional skin, which increases collagen synthesis.

Clinical Features and Treatment of Scleroderma

FRANCESCO BOIN • FREDRICK M. WIGLEY

KEY POINTS

Systemic sclerosis is a multisystem connective tissue disease affecting the skin and internal organs.

The disease process is characterized by chronic inflammation with variable degrees of collagen accumulation (fibrosis) in affected tissues and obliterative vasculopathy of peripheral and visceral vasculature.

It can be associated with high morbidity and mortality in certain subsets, particularly when lungs, heart, gastrointestinal tract, and kidneys are involved.

Effective management of organ-specific disease manifestations is recommended, although no disease-modifying therapy is yet available.

HISTORICAL PERSPECTIVE

Some consider that the first description of systemic sclerosis (scleroderma) was put forth in 1753 by Cario Curzio (Naples, Italy).¹ However, a careful review of the reported case suggests that the diagnosis was really *scleroedema* because of the distribution of the skin changes and the fact that the 17-year-old female improved with bloodletting, warm milk, and small doses of quicksilver. In 1836, Fantonetti (1791-1877), a Milanese physician, became the first to use the word *scleroderma* to designate a skin disease in an adult. However, it is likely that this patient also had *scleroedema*. The first convincing case of scleroderma was reported in 1842; then several acceptable cases were published before 1847, when Gintrac used the term *sclerodermie*, establishing this condition as a specific clinical entity.² By 1860, numerous cases had been reported, and articles reviewing the disease were published. Maurice Raynaud (1834-1881) described a patient with *sclerodermie* and cold-induced “asphyxie locale”—this was the first description of Raynaud’s phenomenon in scleroderma. Sir William Osler described scleroderma while at Johns Hopkins Hospital between 1891 and 1897.³ Osler recognized the systemic nature of the disease and was so impressed with the severity of scleroderma that he wrote:

In its more aggravated forms, diffuse scleroderma is one of the most terrible of all human ills. Like Tithonus, to “whither slowly,” and like him to be “beaten down and marred and wasted” until one is literally a mummy, encased in an ever-shrinking, slowly contracting skin of steel, is a fate not pictured in any tragedy, ancient or modern.

Matsui (Japan, 1924) emphasized the importance of visceral involvement as part of scleroderma based on several

autopsies. Goetz (Capetown, 1945) further confirmed the multisystem involvement and suggested that the disease be named *progressive systemic sclerosis*.⁴

The concept of subtypes of scleroderma began in 1964, when Winterbauer reported cases with the CRST (calcinosis, Raynaud’s phenomenon, sclerodactyly, and telangiectasia) syndrome.⁵ A similar group of patients was reported in 1920 and was named after the authors—the Thiberge-Weissenbach syndrome. Velayos and colleagues recognized that esophageal dysmotility was common in these patients, so it is now called the CREST syndrome.⁶ In 1969, 58 autopsy cases of scleroderma were compared with matched controls.⁷ The organs found to be frequently and significantly involved by this disease were the skin, gastrointestinal tract, lungs, kidneys, skeletal muscle, and pericardium. This report first described the systemic nature of scleroderma vascular disease with findings of both kidney and lung arterial changes. In 1979, Rodnan introduced a clinical method to evaluate the extent of skin disease.⁸ Steen and Medsger with others conducted extensive surveys of large populations of scleroderma patients, defining the clinical course and specific subtypes of disease. In the 1970s, an expert subcommittee established diagnostic criteria, and Leroy and colleagues suggested the classification of two major subsets of disease defined by skin involvement: *limited* and *diffuse*. Later, work by several investigators recognized that scleroderma has an autoimmune basis with occurrence of specific autoantibodies associated with subtypes of disease and useful in predicting disease course.

Scientific work in the modern era has revealed details regarding the pathogenesis of the disease and has led to the recognition that scleroderma is a complex polygenetic autoimmune disease associated with a unique disease process involving tissue fibrosis. Although no drug has yet been discovered with clear disease-modifying properties and ability to fully control the underlying disease process, major progress has been made in managing specific organ disease. The discovery that an angiotensin-converting enzyme inhibitor could reverse the scleroderma renal crisis in the 1970s has changed the course of kidney disease in scleroderma and has improved the survival of patients. Current therapies for gastrointestinal, cardiac, pulmonary, vascular, and interstitial lung disease have improved quality of life and survival.

EPIDEMIOLOGY

Incidence and Prevalence

Scleroderma is a rare disease with an estimated incidence of approximately 18 to 20 cases per million population per

year, and a prevalence of 100 to 300 cases per million population. Reported rates vary by method of ascertainment, population under study, and definition of disease. Scleroderma is found in all races and in various geographic areas, but the prevalence and severity of disease vary among different racial and ethnic groups. The prevalence of scleroderma appears to be greater in the United States, where it has been estimated at 24.2 per 100,000, than in Europe, where recent studies in Iceland, England, France, and Greece have estimated rates ranging from 7.1 to 15.8 per 100,000.⁹ In Australia, estimates are similar to those in the United States, and Japan has a lower reported prevalence—similar to that in Europe.¹⁰ The highest scleroderma prevalence is reported among Choctaw Native Americans, in whom the disease appears to be more severe.¹¹ Several surveys in the United States show that African-Americans have a higher age-specific incidence rate and experience more severe disease than whites.¹² Occurrence is not different from urban to rural areas. Occasional reports have described unusually large numbers of cases of scleroderma observed in restricted geographic regions, suggesting non-random distribution of the disease. For example, in a rural area in the province of Rome, a geographic cluster of scleroderma and disease with related features was reported, suggesting prevalence 1000 times greater than expected.¹³ Likewise, a study in the United Kingdom reported a higher prevalence of scleroderma in three geographic areas clustered near airports compared with other areas of the United Kingdom.¹⁴

The average age at onset is between 35 and 50 years, and the disease is more common among women (3 to 7:1 female-to-male ratio). Disease onset in the elderly is well described; it is uncommon for the disease to become manifest before the age of 25 years. Older age at onset is associated with increased risk for multisystem disease and, in particular, pulmonary arterial hypertension (PAH). A progressive increase in the incidence of scleroderma has been noted with increasing age. Over the period from 1963 to 1982, in Pittsburgh, Pennsylvania, the highest rates of scleroderma were observed between the ages of 45 and 54 years in black women, and between the ages of 55 and 64 years in white women.¹⁵ Younger age at disease diagnosis among black women compared with white women was reported from Detroit, Michigan.⁹

Survival

Mortality among scleroderma patients is high, and most deaths are attributed directly to the disease manifestations.¹⁶ In fact, the prognosis in scleroderma is highly variable, and survival is influenced by disease subtype, degree of internal organ involvement, and comorbid conditions. Factors associated with poor prognosis include diffuse skin disease, the presence of pulmonary disease (particularly PAH), renal involvement, multisystem disease, evidence of heart disease, older age at disease onset, and the presence of anemia. The standardized mortality rate (SMR) is the measure used to assess the relative mortality of a disease in comparison with the general population. Surveys of scleroderma patients report an SMR from 1.46 to 7.1. A survey found that among 284 scleroderma patients who died, the median disease duration as estimated from the onset of Raynaud's

phenomenon until death was 7.1 years for patients with diffuse skin disease, and 15.0 years for those with limited skin disease. Among non-scleroderma-related causes of death are, as expected, infection, malignancy, and cardiovascular events. Although premature atherosclerosis has been implicated as the cause of early death in other inflammatory autoimmune diseases, an increased prevalence of macroscopic coronary artery or cerebrovascular involvement beyond that expected in the general population has not yet been demonstrated in scleroderma.

Several studies suggest that the main cause of death has changed over time. Improved survival in recent years is thought to be secondary to more effective treatments for specific organ-based complications. It seems clear that the natural history of scleroderma renal complications has changed secondary to the use of angiotensin-converting enzyme (ACE) inhibitors for renal crisis. Historically, patients with scleroderma renal crisis had 1-year survival less than 15%.¹⁷ Recent case-control studies conducted after the introduction of ACE inhibitors suggest greater than 85% 1-year survival. Pharmacologic prevention and treatment of interstitial lung disease and PAH are thought to have an impact. Cohort studies have demonstrated improved overall survival among scleroderma patients. At one scleroderma center, 10-year survival from disease diagnosis improved from 54% in the 1972-1981 group to 66% in the 1982-1991 group.¹⁸ Another survey found that 5-year survival among diffuse cutaneous scleroderma patients improved from 69% in 1990-1993 to 84% in 2000-2003 ($P = .018$), whereas 5-year survival among limited cutaneous scleroderma patients remained unchanged at 93% and 91%, respectively.¹⁹

Environmental Exposures

Geographic clustering of scleroderma cases suggests that environmental exposure may be responsible for the disease, but definitive proof is still lacking. Epidemics of scleroderma-like illness following exposure to dietary (L-tryptophan or adulterated rapeseed oil), occupational (silica), or pharmacologic toxins (e.g., bleomycin, gadolinium-based contrast media) support the idea that environmental exposure can trigger a fibrotic disease. Typical scleroderma is found among coal miners and workers exposed to silica, particularly male workers. A meta-analysis of the risk of silica exposure found that the combined estimator of relative risk (CERR) was 1.03 (95% confidence interval [CI], 0.74 to 1.44) in females and 3.02 (95% CI, 1.24 to 7.35) in males.²⁰ Although occupational exposure to solvents (paint thinner or removers, mineral spirits, trichloroethylene, trichloroethane, perchloroethane, gasoline, aliphatic hydrocarbons, halogenated hydrocarbons, and BTX solvents containing benzene, toluene, or xylene) or polyvinyl chloride is reported to be associated with scleroderma, the role of these agents in causing disease is controversial and remains unproven. Likewise, case reports have suggested that silicone present in breast implants has triggered scleroderma, but large epidemiologic surveys have not found a greater incidence of scleroderma than expected in women with breast implants or exposure to silicone. Drugs implicated as potentially causative for systemic sclerosis (SSc)-like illnesses include bleomycin, pentazocine, and cocaine.

Genetic Factors

Although the absolute risk for family clustering remains low (1%), studies from Australia and the United States suggest that a family history of scleroderma increases the risk of disease, with a relative risk of first-degree relatives around 14 and of siblings in the range of 15 to 19.²¹ Genetic factors were investigated by a survey of 42 twin pairs among which at least one twin had scleroderma.²² The overall concordance rate was low at 4.7%, and was similar between monozygotic and dizygotic twin pairs. Although an association between major histocompatibility complex (MHC) alleles and scleroderma has been reported, this has not been confirmed consistently.²³ This finding argues against strong genetic susceptibility and favors a role for environmental and/or epigenetic events.

OVERVIEW OF CLINICAL FEATURES

Diagnostic Criteria

A subcommittee of the American College of Rheumatology (ACR) established diagnostic criteria based on a consensus of experts who evaluated a multicenter survey of scleroderma patients compared with other patient groups (Table 84-1).²⁴ The purpose of these criteria was to provide diagnostic certainty and consistency for research and other documentary exercises. The single finding of thickening of the skin typical of scleroderma proximal to the metacarpophalangeal (MCP) joints of the hands is considered a major criterion confirming the diagnosis. This includes changes on the face, arms, legs, or trunk. If skin thickening is found only distal to the MCP joints, then two of three minor criteria (digital pits, sclerodactyly, and pulmonary fibrosis on chest radiograph) must be present to confirm the diagnosis. These criteria are very specific (98%) for making the diagnosis of scleroderma but are considered too restricted in that they exclude patients with early or mild expression of the disease. Many patients with skin thickening limited to the fingers and some with no skin changes are recognized

to have systemic disease and yet do not meet the ACR criteria. Large longitudinal surveys confirm that a high percentage of patients with definitive Raynaud's phenomenon and typical scleroderma nail-fold capillary changes, along with scleroderma-specific autoantibodies, develop scleroderma within a 2- to 4-year period of follow-up.²⁵ Therefore, although the ACR criteria have a definite role in defining cases for research purposes, the clinician needs to take into account subtle features of the disease to make an early diagnosis for management purposes. Most experts would accept the finding of three of the five features of the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasias) to make a clinical diagnosis of scleroderma. In clinical practice, one needs to recognize that some patients will not develop skin changes and yet they do have systemic disease (systemic sclerosis sine scleroderma), and many patients will present with partial expression of the disease (e.g., Raynaud's with nail-fold changes only) and later will develop well-defined disease. Experts argue that patients with partial expression, especially when a specific scleroderma-related autoantibody is present, should be considered to have a diagnosis of scleroderma and should be treated accordingly.

Classification and Clinical Subsets

The scleroderma disease process is complex, and its clinical expression is very heterogeneous such that the disease is expressed in several distinct clinical phenotypes. Classifying patients into subtypes is useful both for investigative purposes and for clinical practice. A specific subtype can define increased risk for internal organ involvement and overall prognosis. The traditional way to classify patients is by the degree of skin thickening as determined by physical examination. The skin is scored by pinching a fold and deciding whether it is abnormally thickened because of the scleroderma process. A committee of experts decided by consensus that two major groups of patients can be identified based on the distribution of skin changes and associated clinical and laboratory outcomes as observed (Figure 84-1).²⁶ Patients are considered to have *diffuse skin disease* if skin changes are found proximal to the elbows and/or knees or on the trunk, excluding the face. These patients tend to have higher risk of multisystem disease and poor survival. Patients are considered to have *limited disease* if skin changes occur distal to the elbows and/or knees and not on the trunk. Facial skin thickening can be present in the limited group. Some argue that the term *CREST syndrome* should be eliminated, and that these patients should be classified in the limited skin group. Others feel that the CREST syndrome is a unique subtype within the broader group of limited skin diseases with a distinct disease course.

Another less popular classification system divides patients into three groups based on skin changes: limited (fingers only), intermediate (skin to the elbows or knees), and diffuse (skin above the elbows and/or knees and/or trunk). Studies using this classification have found that the intermediate group had distinct clinical outcomes, including an intermediate survival statistic between limited (best) and diffuse (worse).²⁷ A subtype of disease with absence of skin fibrosis has been recognized and is referred to as *scleroderma sine scleroderma*. Serologic studies have shown that the

Table 84-1 Establishing Diagnosis of Scleroderma

ACR Criteria	a. Proximal SS (proximal to MCPs/MTPs)
Must have (a) or two of (b), (c), or (d)	b. Digital pits c. Sclerodactyly d. Pulmonary fibrosis (CXR; HRCT)
CREST Criteria	Calcinosis
Must have three of the five features	Raynaud's phenomenon Esophageal dysmotility Sclerodactyly Telangiectasias
Minor Criteria*†	Definite Raynaud's phenomenon
Must have all three	Abnormal capillary loops Specific scleroderma autoantibody

*Some experts continue to classify patients with minor criteria only as undifferentiated connective tissue disease with scleroderma features.

†Proximal areas include the face. Autoantibody includes anticentromere, antitopoisomerase (Scl-70), and anti-RNA polymerase III.

ACR, American College of Rheumatology; CREST, calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasias; CXR, chest x-ray; HRCT, high-resolution computed tomography; MCPs, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; SS, systemic sclerosis.

Figure 84-1 Classification of scleroderma and clinical subsets. Most experts classify scleroderma into two major groups: limited and diffuse. Limited includes patients with no skin changes (systemic sclerosis “sine” scleroderma), and type I or II, who do not have more proximal limb or truncal involvement.

presence of specific autoantibodies predicts clinical features of the disease, suggesting that the classification might be based on the autoantibody type (see “Natural History”). Patients with early or partial expression of the disease (e.g., Raynaud’s phenomenon alone with nail-fold capillary loop abnormalities) are often diagnosed as having undifferentiated connective tissue disease (UCTD). About 20% of these patients will develop clear features of scleroderma, usually within 2 to 4 years of follow-up.²⁵

Scleroderma patients often have features of another rheumatic or autoimmune disease. These patients are considered to have an *overlap syndrome*. The most common overlap syndromes are polyarthritis, myositis, sicca complex, and hypothyroidism. Less common are primary biliary cirrhosis, autoimmune hepatitis, vasculitis, rheumatoid arthritis, and antineutrophil cytoplasm antibody (ANCA)-associated pauci-immune glomerulonephritis. Mixed connective tissue disease (MCTD) is an overlap syndrome, with features of scleroderma, polymyositis, lupus-like rashes, and rheumatoid-like polyarthritis.

Natural History of Disease

The natural history of scleroderma varies a great deal depending on the specific subtype of disease established in

a patient. Scleroderma tends to be a chronic monophasic illness, unlike systemic lupus erythematosus, which is characterized by quiescence interrupted by sudden disease flares. The pattern of the disease and the degree or type of internal organ involvement are variable but generally can be predicted by the extent of skin affected. Internal organ disease is more severe in patients with the diffuse skin type than in those with limited scleroderma. The disease course is usually indolent in patients with sclerodactyly alone. In these patients, years pass from onset of Raynaud’s phenomenon before obvious organ dysfunction manifests, although explosive multisystem disease can emerge rapidly over several months in patients with widespread skin changes. Likewise, when patients with diffuse skin disease experience skin improvement, new internal organ disease is generally uncommon. The degree of skin thickening varies in extent and progression over time, with some cases stopping after several months with relatively mild disease, and others progressing over years to involve most of the body surface (see “Skin Involvement”).

Patients classified in the *limited scleroderma* group may have intermediate skin involvement, with skin extending over the hands and forearms or lower legs but not over the trunk. These patients appear to have an intermediate disease course that is not as severe as that of patients with

widespread skin disease. The intermediate group has decreased survival compared with patients with only sclerodactyly. Although the degree of skin disease provides a rough guide by which to predict disease course, many exceptions have been noted. Variability is associated with other clinically defined factors, including age, gender, and racial/ethnic background. Late age at onset increases the risks for PAH and poor survival. Males may have a more aggressive disease course than females. African-American or Native American race predicts a worse disease course and worse multisystem disease.⁹

GENERAL PRINCIPLES OF DISEASE EVALUATION

Measuring Disease Activity and Severity

One of the challenges in studying or caring for patients with scleroderma consists of determining and measuring disease activity, severity, and damage. These measures are not independent of each other and thus cannot be considered in isolation. Activity is a measure of ongoing disease that is dynamic and reversible; it is a direct reflection of ongoing biologic processes such as autoimmune-mediated inflammation or progressive tissue fibrosis. Severity is a measure of the impact of damage on the whole person or a specific organ at any given time. In the extreme, severity is a measure of irreversible end-stage damage. It is important to distinguish reversible disease activity from irreversible damage in that both can cause clinical distress, yet intervention differs for the two. Patients with scleroderma accumulate irreversible damage over time, thus the measure of activity is best done in early disease, when disease has the potential of being reversed.

Measurement of changes in skin thickness (modified Rodnan skin score) is used as a surrogate measure of disease severity and a predictor of extent of organ involvement and overall prognosis (see skin manifestation section).²⁸ It is also used as a quantifiable, easily obtainable, and valid score, changing over time in response to therapy. Thus, the skin score is now used as a measure of disease activity and is employed in clinical trials as a primary outcome measure. In patients with diffuse skin disease, improvement in skin score is associated with better clinical outcome. A core set of items covering 11 domains (skin, musculoskeletal, cardiac, pulmonary, renal, gastrointestinal, health-related quality of life measures, global health, Raynaud's phenomenon, digital ulcers, and the biomarkers erythrocyte sedimentation rate and C-reactive protein) is now considered to provide the minimum clinically relevant treatment effect values, as defined by consensus of experts in the field.²⁹ More detailed scales for specific organs are also in use. For example, a skin assessment tool combines the modified Rodnan skin score with a visual analogue score (VAS) of the patient's assessment of skin activity, a VAS score of the physician's assessment of skin activity, and measures obtained by a durometer.³⁰ A gastrointestinal scale has been developed to define mild to severe gastrointestinal disease.³¹ Experts who reviewed current outcome measures in assessing PAH as related to scleroderma decided that lung vascular and pulmonary arterial pressures and cardiac function as measured by right heart catheterization and echocardiography;

exercise testing as measured by 6-minute walk and oxygen saturation with exercise, New York Heart Association functional class, severity of dyspnea on a VAS, and measures of quality of life and function obtained by Short Form 36 and the Health Assessment Questionnaire and Disability Index (HAQ-DI); and physician global scale as measured by survival are all important measures. Other outcome measures that are considered valid include Raynaud's condition score for Raynaud's severity, forced vital capacity, and Mahler's dyspnea index to follow interstitial lung disease, serum creatinine, blood pressure, and complete blood count during a scleroderma renal crisis, as well as serum creatine phosphokinase to follow muscle disease.

A scleroderma severity scale has been developed by Medsger to assess disease severity status in individual patients both at a given time and longitudinally (Table 84-2).³² This scale is based on scoring that ranges from 0 (normal) to 4 (end-stage) for each organ system involved in scleroderma, including a general measure, along with measures of the peripheral vascular system, skin, joints and tendons, gastrointestinal tract, lung, heart, and kidney. This severity scale is now used by many experts to define the status of a patient in clinical trials and in research investigating risk for clinical outcomes.

The Health Assessment Questionnaire and Disability Index (HAQ-DI) is a self-administered tool initially developed for rheumatoid arthritis to measure functional impairment; it has been validated and used in scleroderma as well, where it correlates with objective physical signs and reflects the disease course. Higher degrees of impairment are found by HAQ scores in scleroderma patients with diffuse skin disease, higher skin scores, abnormal hand function, presence of myopathy or friction rubs, and joint pain.³³ Change in the HAQ score occurs with changes in skin involvement and progressive organ disease.³⁴ The HAQ is useful in evaluating patients with Raynaud's and correlates with the severity and presence of digital ulcers. VAS instruments that assess disease in various domains specific for scleroderma are added to the HAQ to focus on scleroderma-specific issues, including measures of Raynaud's and digital ulcers. In addition, the Short Form 36 survey, a simple self-report tool composed of 36 items in 8 domains, is used to assess health-related quality of life.

Developing an activity scale is much more challenging than establishing severity measures. Attempts include evaluating changes in skin score and evidence of active lung disease and documenting congestive heart failure or a scleroderma renal crisis. A composite score generated as a physician global assessment has been used to measure disease activity. This simple global score has merit but is influenced, besides activity, by organ severity and irreversible damage.³⁵ A European study group developed the Valentini disease activity index, which currently is used in clinical studies.³⁶ This index provides more of an organ-specific assessment than a measure of global activity. The Medsger disease severity scale has the potential to measure activity if used in studies with serial observations, when individual organ scales can be combined into a composite score. Intermediate clinical and serologic biomarkers are under investigation as candidates to define and predict disease activity and prognosis, but none has proved reliable or valid. Measures of acute phase factors (e.g., erythrocyte

Table 84-2 Medsger Systemic Sclerosis Severity Scale*

Organ System	0 (Normal)	1 (Mild)	2 (Moderate)	3 (Severe)	4 (End Stage)
General	Wt loss <5%; Ht 37%+; Hb 12.3+ g/dL	Wt loss 5%-10%; Ht 33%-37%; Hb 11.0-12.2 g/dL	Wt loss 10%-15%; Ht 29%-33%; Hb 9.7-10.9 g/dL	Wt loss 15%-20%; Ht 25%-29%; Hb 8.3-9.6 g/dL	Wt loss 20+%; Ht 25%; Hb <8.3 g/dL
Peripheral vascular	No Raynaud's; Raynaud's not requiring vasodilators	Raynaud's requiring vasodilators	Digital pitting scars	Digital tip ulcerations	Digital gangrene
Skin	TSS 0	TSS 1-14	TSS 15-29	TSS 30-39	TSS 40+
Joint/tendon	FTP 0-0.9 cm	FTP 1.0-1.9 cm	FTP 2.0-3.9 cm	FTP 4.0-4.9 cm	FTP 5.0+ cm
Muscle	Normal proximal muscle strength	Proximal weakness, mild	Proximal weakness, moderate	Proximal weakness, severe	Ambulation aids required
Gastrointestinal tract	Normal esophagogram; normal small bowel series	Distal esophageal hypoperistalsis; small bowel series abnormal	Antibiotics required for bacterial overgrowth	Malabsorption syndrome; episodes of pseudo-obstruction	Hyperalimentation required
Lung	DLCO 80+%; FVC 80+%; no fibrosis on radiograph; sPAP <35 mm Hg	DLCO 70%-79%; FVC 70%-79%; basilar rales; fibrosis on radiograph; sPAP 35-49 mm Hg	DLCO 50%-69%; FVC 50%-69%; sPAP 50-64 mm Hg	DLCO <50%; FVC <50%; sPAP 65+ mm Hg	Oxygen required
Heart	ECG normal; LVEF 50+%	ECG conduction defect; LVEF 45%-49%	ECG arrhythmia; LVEF 40%-44%	ECG arrhythmia requiring therapy; LVEF 30%-40%	CHF; LVEF <30%
Kidney	No history of SRC with serum creatinine <1.3 mg/dL	History of SRC with serum creatinine <1.5 mg/dL	History of SRC with serum creatinine 1.5-2.4 mg/dL	History of SRC with serum creatinine 2.5-5.0 mg/dL	History of SRC with serum creatinine >5.0 mg/dL or dialysis required

*If two items are included for a severity grade, only one is required for the patient to be scored as having disease of that severity level.

CHF, congestive heart failure; DLCO, diffusing capacity for carbon monoxide, % predicted; ECG, electrocardiogram; FTP, fingertip-to-palm distance in flexion; FVC, forced vital capacity, % predicted; Hb, hemoglobin; Ht, hematocrit; LVEF, left ventricular ejection fraction; sPAP, estimated pulmonary artery pressure by Doppler echo; SRC, scleroderma renal crisis; TSS, total skin score; Wt, weight.

sedimentation rate, C-reactive protein) are nonspecific but are included by expert consensus in some systems designed to measure disease activity. Currently, no “gold standard” is available to measure disease activity in scleroderma, and defining biomarkers or other measures of disease activity remains a major challenge.

Autoantibodies

Measurement of the autoantibodies present in scleroderma can be helpful in determining the clinical features and prognosis of the disease, in that specific scleroderma-related autoantibodies have been established as strong predictors of disease outcome and the pattern of organ complications

(Table 84-3).³⁷ The three most frequently observed types of scleroderma-specific autoantibodies are anticentromere, antitopoisomerase I, and anti-RNA polymerase III antibodies.

Anticentromere patients tend to be older white women. Skin disease usually is limited and most often involves just the fingers. The disease course is indolent, and often the diagnosis is delayed until anticentromere antibodies are discovered or late organ disease becomes evident. Patients frequently develop features of the CREST syndrome. Subcutaneous calcinosis is a late manifestation, appearing in areas such as small clusters on the fingers and along the forearm and anterior lower leg. Raynaud's phenomenon can become severe and is associated with increased risk for

Table 84-3 Autoantibodies and Associated Phenotypes in Scleroderma

Antigen	Subtype	Clinical Phenotype
Topoisomerase 1 (Scl70)	Diffuse	Pulmonary fibrosis, cardiac involvement
Centromere (protein B, C)	Limited	Severe digital ischemia, PAH, sicca syndrome, calcinosis
RNA polymerase III	Diffuse	Severe skin disease, tendon rubs, renal crisis (±sine scleroderma)
U3-RNP (fibrillarin)	Diffuse or limited	Primary PAH; esophageal, cardiac, and renal involvement; muscular disease
Th/To	Limited	Pulmonary fibrosis, rare renal crisis, lower GI dysfunction
B23	Diffuse or limited	PAH, lung disease
Cardiolipin, β_2 GPI	Limited	PAH, digital loss
PM/Scl	Overlap	Myositis, pulmonary fibrosis, acro-osteolysis
U1-RNP	Overlap	SLE, inflammatory arthritis, pulmonary fibrosis

GI, gastrointestinal; GPI, glycoprotein I; PAH, pulmonary arterial hypertension; RNA, ribonucleic acid; RNP, ribonucleoprotein particle; SLE, systemic lupus erythematosus.

macrovascular disease. Higher risk for digital gangrene and amputation is noted in the anticentromere-positive group. Interstitial lung disease is less common and is isolated and progressive; pulmonary vascular disease with PAH and right heart failure occur in a significant proportion of patients. Overall, however, anticentromere antibodies generally are predictors of a favorable prognosis. The presence of anticentromere antibodies can also be seen in patients with primary Sjögren's syndrome who do not have scleroderma.

Antitopoisomerase I antibodies are seen in 30% of African-American patients and are correlated with a poor prognosis and higher scleroderma-related mortality. Interstitial lung disease (ILD) is highly associated with anti-topoisomerase, independent of the degree of skin disease. Patients usually have diffuse skin disease and are at risk for rapid skin changes and renal crisis, usually in the first few years from disease onset. Raynaud's phenomenon may be the first symptom, followed in the first years of disease by skin changes and joint-tendon involvement leading to contractures, particularly in the fingers and elbows. The degree of skin thickening varies a great deal in these patients, but usually the level of severity of skin involvement is established in the first 1 to 3 years of disease.

Anti-RNA polymerase III antibodies are associated with rapid and aggressive diffuse skin disease and renal involvement. These patients have the worst cutaneous involvement with rapid widespread skin disease associated with signs and symptoms of deep tissue fibrosis involving joints, tendons, and muscles. Flexion contractures of fingers, wrist, elbows, shoulders, hips, knees, and ankles are complications that can occur within a few months of onset of disease activity. Friction rubs are common. A "fibrosing" myopathy without inflammation, along with skin and joint disease, leads to loss of strength and flexibility. Significant disability occurs in early disease. Anti-RNA polymerase III-positive patients are not likely to have severe gastrointestinal disease and are relatively protected from developing ILD or pulmonary vascular disease. However, they are at high risk (approximately 25% to 40% of patients) for developing scleroderma renal disease with hypertensive crisis. Risk is greatest in the early years, when skin is rapidly changing. Heart disease can be a late complication, but major disability from skin and deep tissue disease is the most worrisome long-term problem in this subtype of scleroderma.

Other antinucleolar antibodies are found among subgroups of patients with scleroderma and are associated with specific clinical phenotypes and clinical outcomes. Of these, anti-Th/To antibodies and anti-PM/Scl antibodies are associated with limited skin disease, whereas anti-U3-RNP (fibrillarin) antibodies are associated with diffuse disease. Anti-Th/To is at increased risk for development of severe ILD and pulmonary hypertension. Anti-U3-RNP is another predictor of a less favorable prognosis with a higher frequency of internal organ involvement, including interstitial lung disease, PAH, and renal crisis. It is frequently present in African-Americans and is associated with diffuse skin disease and poor prognosis. Hyperpigmented and hypopigmented skin changes are common, and contractures of large joints associated with inflammatory or fibrotic muscle disease lead to significant morbidity. Cardiac disease is often

subclinical until late-stage disease, when both right and left heart failure can occur.

Anti-PM/Scl, anti-Ku, and anti-U1-RNP antibodies are seen mainly in patients with overlap syndromes. The presence of anti-Pm/Scl is associated with acute onset of weakness due to inflammatory muscle disease and higher risk for interstitial lung disease. Anti-Ku positivity has been demonstrated to be strongly associated with muscle and joint involvement. Anti-U1-RNP is seen in patients with mixed connective tissue disease and is common among African-Americans with limited scleroderma. Polyarthritis, myositis, and lupus with skin or renal involvement are common complications. A subset can develop diffuse skin disease, and risk for late onset of PAH is increased overall. Although an uncommon anti-B23 autoantibody is associated with pulmonary arterial hypertension, up to 11% of patients with scleroderma can test negative for antinuclear antibodies.

CLINICAL MANIFESTATIONS AND TREATMENT

General Principles of Management

Several basic principles can be of help in managing patients with scleroderma. The first is that scleroderma encompasses subsets of disease, each with a unique clinical phenotype; thus carefully determining the specific subtype of the patient sets the scene for deciding therapy. Clinical problems and disease activity in scleroderma are highly variable in expression, even within a given subtype. This variability is thought to be secondary to different susceptibility to, or risk for, systemic complications. It is also due to the presence of a dynamic biologic process unique to scleroderma. Therefore, patients move through stages of the disease process with disease activity that varies with time and can shift in nature. Signs of classic inflammatory events are often present during the initial phase of the disease, but later, an indolent subclinical fibrotic process is dominant and gradually causes organ damage. Although the skin may be the site of the most dramatic physical findings, scleroderma is a multisystem disease, and the physician must search for early organ-based complications, including cardiopulmonary, gastrointestinal, renal, or musculoskeletal involvement. Understanding the shortcomings of current investigations, not getting locked into "traditional" therapy, focusing on an organ-specific approach, and defining the disease subtype and level of disease activity are most important in establishing optimal management. Although no good studies have been conducted to prove the effectiveness of this approach, it seems reasonable to use combination therapy with rapid control of the inflammatory immune process early on, followed by maintenance immunosuppression for an extended time. The anti-inflammatory program is then coupled with organ-specific therapy (see later sections). The missing component in this comprehensive approach is the availability of a direct antifibrotic agent able to prevent the progression of fibrosis once the inflammatory phase is under control. Obviously, early intervention is most important for success; once irreversible tissue or organ damage is noted, supportive care becomes the main and often the only option.

RAYNAUD'S PHENOMENON

KEY POINTS

Raynaud's phenomenon (RP) is common in the general population and usually presents with a benign clinical course.

In scleroderma, RP is more clinically symptomatic and can be associated with manifestations of digital ischemia.

Abnormal vasomotor regulation and progressive endothelial and structural vessel disease occur in RP associated with scleroderma.

Treatment for RP must include control of excessive vasoreactivity, modification of structural vascular disease, and prevention of microthrombotic events.

Raynaud's phenomenon (RP) is an exaggerated vascular response of the digital arterial circulation triggered by cold ambient temperature and emotional stress. The diagnosis of RP is based on a history of excessive cold sensitivity and recurrent events of sharply demarcated pallor and/or cyanosis of the skin of the digits ([Figure 84-2](#)). Blanching reflects digital arterial vasospasm, and cyanosis occurs secondary to the deoxygenation of sluggish venous blood flow. Some skin blushing (redness) may follow owing to reactive hyperemia after regular blood flow has been restored. Raynaud's phenomenon occurs in 3% to 15% of the general population. It is more common among females (3 to 4:1) and is likely to begin before 20 years of age. During cold exposure (particularly during shifting temperatures and winter months), Raynaud's attacks increase in frequency and intensity. Raynaud's phenomenon can be categorized clinically into primary and secondary forms ([Figure 84-3](#)). Primary RP occurs when no disease process is associated with recurrent vasospastic events. Distinguishing primary RP from that associated with an underlying disorder is frequently challenging. Young age at onset (<20 years), symmetric manifestations of symptoms, mild to moderate severity, no association with digital ulceration or tissue gangrene, normal nail-fold capillary examination, and a negative antinuclear antibody (ANA) titer are all indicative of primary RP.³⁸ Secondary RP occurs in a variety of settings, including connective tissues disorders and other rheumatic

Figure 84-2 Active Raynaud's phenomenon with well-demarcated pallor at the fingertips in a scleroderma patient.

conditions, occupational trauma (e.g., hypothenar hammer syndrome), the use of certain drugs (e.g., antimigraine agents, ergotamine derivatives, bleomycin), increased blood viscosity, and compressive or obstructive vascular disease (e.g., thoracic outlet syndrome, atherosclerosis, thromboangiitis obliterans).

Nail-fold capillaroscopy is the tool most commonly used at the bedside to distinguish patients with primary RP from those with scleroderma or another rheumatic disease. Maricq and associates first described the abnormal pattern of nail-fold capillary vessels seen in scleroderma.³⁹ The simplest method of detection is to coat the skin of the nail fold with immersion oil and then view the area using a bifocal dissecting microscope or a hand-held device such as an ophthalmoscope set at 20 or 40 diopters. A computerized nail-fold videocapillaroscopy technique is used in specialty centers. This technique provides enhanced digital images that can assess local blood flow and follow the disease course.⁴⁰ Although patients with primary RP may have normal, thin, palisading nail-fold capillary loops ([Figure 84-4](#)), in secondary RP, capillary loop dilation/enlargements and dropouts represent the salient features. Patterns of capillary abnormalities appear to correlate with the course of systemic disease manifestations. Capillary dilation (giant capillaries), microhemorrhages, and some disorganization of the capillary network are typical of early disease; dropouts, avascular areas, and signs of neoangiogenesis with bizarre architectural distortion manifest at later stages of scleroderma.^{41,42} Approximately 20% to 30% of patients with RP and abnormal nail-fold capillary changes will develop clinical features of scleroderma, usually within a 2- to 3-year period.²⁵ Patients presenting with RP, nail-fold capillary changes, and the presence of a scleroderma-related autoantibody have a 70% to 80% chance of developing scleroderma within 2 to 3 years from presentation. Therefore, capillaroscopy represents an important standard tool that can be used to examine patients presenting with RP.

In scleroderma, RP and digital ischemia are the clinical manifestations of both fixed structural vascular disease and abnormal regulation of local vasomotor control. Cold-induced vasoconstriction of peripheral blood vessels normally occurs via sympathetic stimulation. Abnormal thermoregulation is associated with a nonvasculitic vasculopathy characterized by endothelial dysfunction and a fibrotic proliferation, which produces an increase in collagen content of the intima of small and medium vessels and causes loss of vessel flexibility and obliteration of their lumina. Digital pitting with loss of fingertip tissue and small, painful, superficial ulcerations are very common and usually are noted secondary to disease affecting the small arteries and arterioles of the skin ([Figure 84-5](#)). Large, deep ulceration of the distal portion of the finger is a consequence of larger-vessel (e.g., digital artery) occlusion associated with severe vasospasm. The latter event usually presents as a sharp demarcation of the distal digit with intense, localized pain secondary to ischemia. Failure to reverse these events may lead to loss of the whole digit or limb secondary to deep tissue infarction.

Although a number of methods may be used to objectively score attacks of RP, no test is considered practical or reproducible enough to replace the clinical criteria for diagnosis and management. Patients with an active RP attack

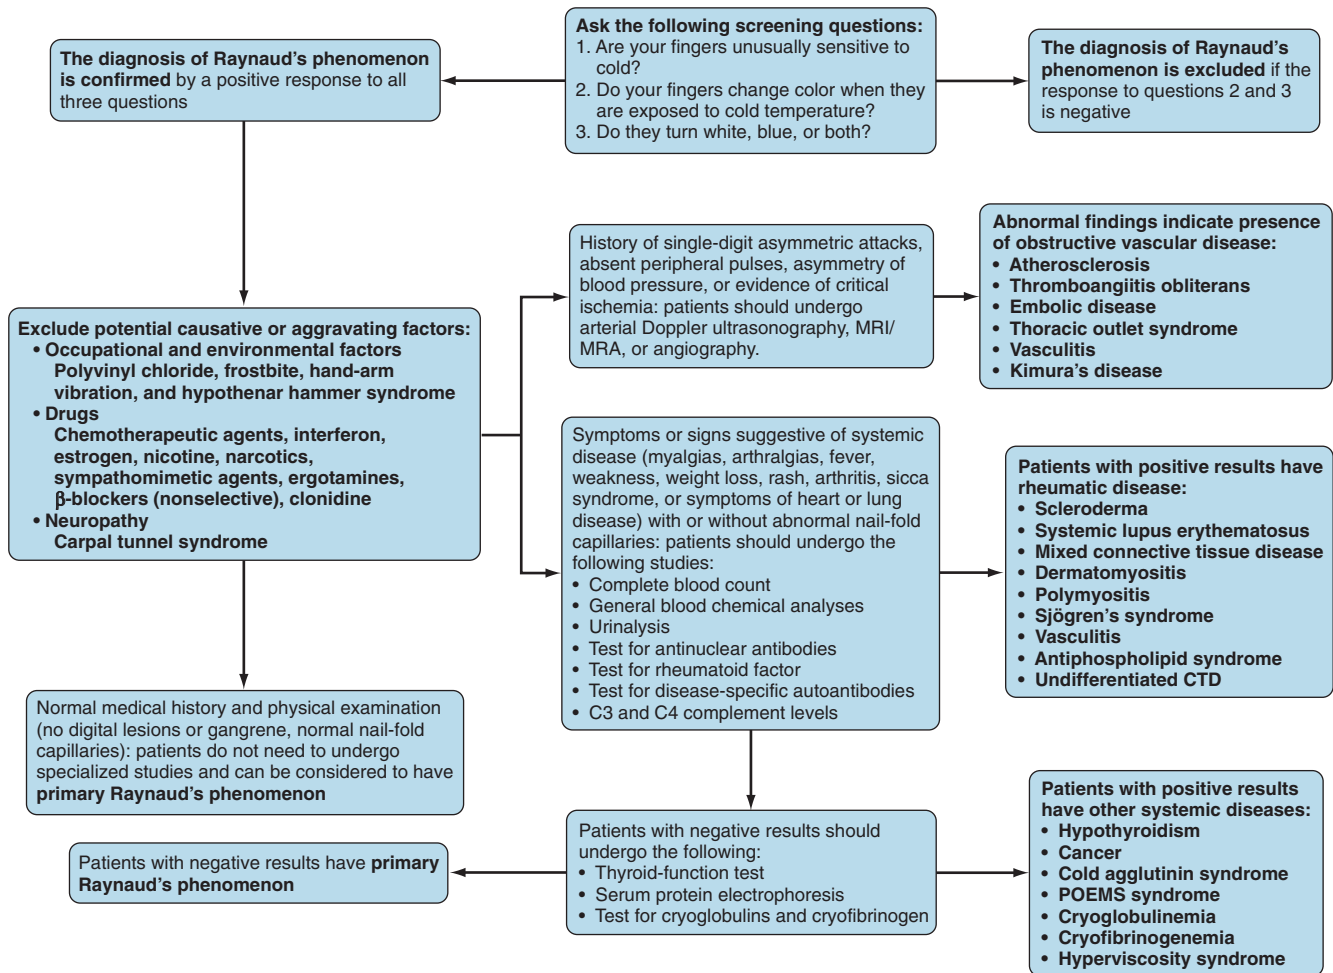

Figure 84-3 Approach to diagnosis of Raynaud's phenomenon. CTD, connective tissue disease; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

will present with coolness of the involved distal fingertips and/or toes, which can be associated with a line of demarcation of skin pallor or cyanosis. In later stages of severe RP, if left untreated, one may find signs of critical digital ischemia resulting in painful and unremitting digital ulcerations. Such findings warrant immediate medical treatment. Several methods may be used to assess the severity of RP. Traditionally, the patient is asked to use a diary to record the frequency and duration of attacks during days of usual activity. Raynaud's condition score (RCS) is a patient-based measure that takes into account the impact of RP on the patient, including pain, discomfort, and effect on daily function. Other laboratory-based measures, including laser Doppler, thermography, and plethysmography methods, are used in an attempt to obtain objective data.

Treatment of Raynaud's Phenomenon and Digital Ischemia

The primary goal in the management of RP is prevention of digital ischemia through the use of nonpharmacologic and pharmacologic measures (Figure 84-6). In the setting of acute digital ischemia, rapid intervention using both treatment modalities is required. The primary and most important nonpharmacologic therapy for prevention is avoidance

of cold ambient temperatures, particularly transitioning from a warm or hot environment to a cold one. A warm ambient temperature reduces the frequency and severity of RP. All patients with RP should understand that clothing should be layered and loose-fitting, with the goal of maintaining a warm core body temperature, not just warmth of the affected extremities. Patients who have an acute ischemic event are best treated with rest in a warm environment (home or hospital), insulated from cold temperatures. Other potential therapies include minimizing emotional distress (reducing sympathetic tone) and avoiding aggravating factors such as smoking, sympathomimetic drugs (e.g., preparations for the common cold), migraine headache medications (e.g., serotonin agonists), and nonselective β -blockers (e.g., propranolol). Although behavioral therapies (biofeedback, autogenic training, and classical conditioning) are reported to be helpful, their benefit is controversial, and they play no role in the management of acute ischemia related to scleroderma.⁴³ In fact, biofeedback alone is not helpful for primary RP.

Drug therapy for RP in scleroderma includes the use of a variety of oral or systemic vasodilators. Calcium channel blockers are considered to be first-line therapeutic agents in the treatment of RP. This class of medication works primarily by inducing arterial vasodilation through direct

Figure 84-4 Patterns of nail-fold capillary abnormalities assessed by videocapillaroscopy in scleroderma patients. *Top right*, “Early pattern” shows the presence of few enlarged/giant capillaries, few capillary hemorrhages, and no evident loss or distortion of capillaries. *Bottom left*, “Active pattern” presents with frequent dilated capillary loops, frequent microhemorrhages, moderate loss of capillaries, and mild disorganization of the capillary architecture. *Bottom right*, “Late pattern” is characterized by severe loss of capillaries with avascular areas, ramified/bushy capillaries (neovascularization), and disorganization of the normal capillary architecture. G, giant capillaries; L, loss of capillaries; M, microhemorrhages; N, neovascularization; SSc, systemic sclerosis. (Courtesy Professor Maurizio Cutolo.)

inhibition of contraction of vessel smooth muscle cells; however, these agents provide additional benefits by reducing oxidative and inhibiting platelet activation.^{44,45} Most published studies evaluating the efficacy of calcium channel blockers in RP have employed dihydropyridines (e.g., nifedipine, amlodipine, nisoldipine, isradipine, felodipine), and few have looked at nondihydropyridines, which appear to be more efficacious in primary than in secondary RP.^{46,47} A meta-analysis of 17 studies evaluating the efficacy of short- and long-acting formulations of calcium channel blockers reported a 33% reduction in attack severity and a near 50% reduction in the number of attacks per week.⁴⁸ The current recommendation is to use an extended-release formulation of a calcium channel blocker for treatment of nonurgent RP. The dose should be titrated to clinical efficacy, but common side effects (hypotension, headache, pedal edema) should be monitored. For urgent cases of RP, a short-acting formulation of the medication is preferred, but titration should be carefully monitored. Although calcium channel blockers are the agents most likely to be effective, a host of other vasodilators are used, including nitrates, phosphodiesterase-5 inhibitors (e.g., sildenafil), intravenous prostaglandins, and sympatholytic agents (e.g., prazosin).

Among other agents being tested in the treatment of RP are drugs that enhance nitric oxide availability—serotonin uptake blockers (e.g., fluoxetine), Rho-kinase inhibitors, local injection of botulinum toxin (Botox), antioxidants (acetylcysteine), angiotensin receptor blockers, and selective α_2 -adrenergic receptor antagonists. A combination of

these agents, if tolerated, can be used in refractory cases. Various formulations of topical and oral nitroglycerin are employed.^{49,50} Although some degree of efficacy is obtained, use of nitroglycerin is limited by substantial side effects, including headache, dizziness, and local skin irritation. The cyclic guanine monophosphate phosphodiesterase-5 inhibitors are thought to be effective in the treatment of RP by sustaining the vasodilatory effect of nitric oxide.^{51,52} Studies using phosphodiesterase inhibitors have reported variable effects, and the ideal drug and dosing have not yet been defined. Despite the theoretical advantage of angiotensin-converting enzyme (ACE) inhibitors, a study of quinapril showed that these medications did not affect the occurrence of digital ulcers or the frequency or severity of RP episodes.⁵³ Thus, although ACEs are critical for the treatment of a scleroderma renal crisis (see renal section), they do not have a major role in the management of RP.

New emphasis is being placed on prevention of scleroderma vascular disease through the use of immunosuppressive and vasoprotective drugs. HMG-CoA (3-hydroxy-3-methylglutaryl-coenzyme A) reductase inhibitors (statins) can modify progression of vascular injury and can prevent vascular ischemia through different pleiotropic functions, as by improvement of endothelial dysfunction, reduction of clotting, and introduction of some anti-inflammatory effects.^{54,55} Data suggest that statins may increase the number of endothelial progenitor cells and may improve vascular remodeling after injury.^{56,57} In a randomized, placebo-controlled study of scleroderma patients with secondary RP,

Figure 84-5 Scleroderma and Raynaud's phenomenon can be associated with digital ulcerations and severe digital ischemia. **A**, Traumatic ulcers over the proximal interphalangeal joints. **B** and **C**, Ischemic digital ulcerations secondary to small arterial disease. **D**, Digital gangrene secondary to macrovascular disease.

statin use significantly decreased the number of digital ulcers formed.⁵⁸

Intravenous infusions of vasodilating prostaglandins (alprostadil, epoprostenol, iloprost, treprostinil) reduce the severity and frequency of Raynaud's attacks and are most helpful during periods of sustained critical ischemia. These prostaglandins are efficacious in the treatment of RP because of their strong vasodilating effect, inhibition of platelet aggregation, and enhancement of vascular function through other mechanisms. Intravenous prostacyclins can be given intermittently to patients with scleroderma during winter months or throughout the year, or they can be used acutely during a vascular crisis. Oral prostaglandins have variable absorption and are not yet available.

Endothelin-1 is strongly implicated in the pathogenesis of RP and the vascular disease of scleroderma.⁵⁹ Bosentan, an endothelin-1 receptor blocker, was studied in a randomized, placebo-controlled, double-blind multicenter study that showed efficacy in preventing new digital ulcers, along with improved hand function, but it did not improve healing of existing ulcers compared with placebo.⁶⁰

Sympathectomy is a viable option for patients with RP who are unresponsive to medical therapy; it should be considered as acute intervention during a critical ischemic event. Localized digital sympathectomy with lysis of fibrosis around the vessel is effective for acute ischemia and has mostly replaced cervical sympathectomy.^{61,62} Responses to sympathectomies suggest that the long-term benefit derived from these interventions is limited. In fact, Raynaud's attacks eventually recur, and medical therapy is needed to prevent new events.

Careful assessment for correctable macrovascular disease should be done when confronted with acute digital ischemia, particularly when the whole finger is demarcated, or when the event involves a lower extremity. In this setting, appropriate studies such as arterial Doppler ultrasound or angiographic imaging are warranted. If macrovascular disease is present, vascular surgery may help to alleviate the occlusive process. Preferential involvement of the ulnar artery has been reported in scleroderma patients.⁶³

Patients with critical digital ischemia should be hospitalized to reduce vasospastic activity, maintain warmth, and permit rapid initiation of vasodilator therapy. Intravenous vasodilating prostaglandins can be infused to maximize vasodilation. Antiplatelet therapy with low-dose aspirin may be useful, but its benefit is unproven in the acute setting. Heparinization may be considered during acute ischemic crises of the digits, but chronic anticoagulation in scleroderma is not recommended. Chemical sympathectomy of the affected digit, performed by local infiltration with lidocaine or bupivacaine, may provide immediate relief. For refractory cases, a surgical approach to digital sympathectomy is used.

Ischemic digital lesions should be treated with topical antibiotics and daily cleansing with soap and water. Débridement procedures should be performed very cautiously because tissue trauma may extend the injury owing to the avascular nature of the digital tissue. Digital lesions that progress to dry gangrene should be permitted to undergo autoamputation. Surgical amputation is best offered only for intractable pain or deep tissue infection.

SKIN INVOLVEMENT

The most overt clinical manifestation of scleroderma is skin disease. The degree of involvement can vary among patients, and involvement can change in severity and distribution over time in the same individual. Almost every scleroderma patient presents with skin thickening and hardening due to increased collagen and extracellular matrix deposition in the dermis. The distribution of skin changes is characteristic, with more frequent and intense involvement of fingers, hands, forearms, distal legs, feet, and face, and, to a lesser degree, the proximal limbs and anterior trunk. Sparing of the midback is typical. Scleroderma is classically subdivided into *limited* and *diffuse* cutaneous forms (Figure 84-7). Limited scleroderma is defined by skin thickening restricted to the face and limbs distally to the elbows and knees. Commonly, in this form of the disease, only the fingers and the face are involved. In contrast, diffuse cutaneous involvement is characterized by widespread skin thickening, including proximal limbs and truncal areas. Proximal skin involvement defines the diffuse cutaneous subset but may be absent in early stages of disease. Signs of skin thickening are not apparent in the setting of other disease manifestations (e.g., Raynaud's phenomenon, nail-fold capillary abnormalities), nor is evidence of internal organ involvement. This clinical presentation is referred to as *systemic sclerosis sine scleroderma*. Traditionally, patients are clustered into limited and diffuse skin subsets, but evidence suggests the existence of an intermediate group of patients. Each subset of disease defined by the degree of skin thickening has a unique pattern of disease manifestation and risk for specific clinical outcomes. Therefore, expression of skin disease can be used as a predictor or a "clinical biomarker" of the disease course. The variable degree of skin involvement can be quantified by physical examination. The most widely accepted scoring system (modified Rodnan skin score) is applied by pinching the skin in 17 different body areas and subjectively averaging the thickness of each specific site from 0 = normal to 3 = very thick (Figure 84-8). The skin score (maximum, 51) is a useful clinical measurement tool that can be used to quantify the severity of skin disease.²⁸ Although the overall extent of skin involvement as measured by the skin score can predict certain clinical outcomes, it does not define the quality of the skin process nor the level of disease activity at any single point in time. Therefore, it is important to follow the skin score over time and to measure changes sequentially to monitor disease progression.

Cutaneous involvement in scleroderma begins with clinical signs of inflammation. This is called the *edematous phase* because it is characterized by nonpitting edema of affected body areas. In limited scleroderma, this event is mild and is restricted to the digits; however, in the diffuse form of the disease, cutaneous swelling and edema can be widespread and so impressive in the limbs as to mimic a fluid overload state such as congestive heart failure. Edema can also cause local tissue compression. For example, upon involvement of the wrist area, scleroderma patients are not infrequently diagnosed with carpal tunnel syndrome (especially at disease onset) to explain hand and wrist discomfort. In association with edema, signs and symptoms of inflammation are

Figure 84-7 Skin involvement in scleroderma is subdivided into “limited” and “diffuse” cutaneous forms. **A**, Sclerodactyly in limited cutaneous disease. **B**, Trunical changes in diffuse cutaneous disease. **C**, Inflammatory signs in early active skin disease. **D**, Finger contracture in the chronic fibrotic phase of skin involvement in scleroderma.

common. Erythema of the skin and intense pruritus and pain (see [Figure 84-7C](#)) are characteristic of advancing active diffuse skin disease. This pain has a neuropathic quality with a reported “pins and needles” sensation. The disease process leads to loss of skin appendages, as well as decreased hair growth and loss of sweat and exocrine glands; thus the skin surface becomes dry and uncomfortable. Small papules can be seen in areas of trauma as the result of scratching, giving the surface a cobblestone texture. The

edematous phase continues for several weeks but eventually gives way to a fibrotic stage, with protracted activity that may last months or years.

During the fibrotic phase, acute inflammation is clinically less obvious, and deposition in the dermis of excessive collagen and other extracellular material thickens the skin, making it inflexible and causing further loss of skin appendages. Fibrosis extends beyond the dermis into the deeper layers with loss of subcutaneous adipose tissue

Figure 84-8 Method used to semi-quantify skin thickness in scleroderma. The modified Rodnan skin score is obtained by clinical palpation of 17 different body areas (fingers, hands, forearms, upper arms, chest, abdomen, thighs, lower legs, and feet) and subjective averaging of the thickness of each specific site: 0 = normal (**A**); 1 = mild (**B**); 2 = moderate (**C**); and 3 = severe (**D**). The maximum score is 51.

(lipodystrophy). In late stages of the disease, skin actually thins with atrophy and has a noninflammatory bound-down appearance. Deeper tissue fibrosis causes permanent contractures around joints or may involve underlying muscle, causing a myopathy (see [Figure 84-7D](#)). Patients with diffuse cutaneous scleroderma develop the most dramatic widespread skin changes; those with limited skin disease may note only puffy fingers and digital thickening typical of sclerodactyly. A masked facies, small oral and orbital apertures, and vertical furrowing of the perioral skin are consequences of skin and soft tissue fibrosis. In some patients, gum atrophy and facial skin tightening make the front teeth appear more prominent. Flexion contractures of fingers, wrists, and elbows often appear secondary to dermal sclerosis and fibrosis with atrophy of underlying tissues. Skin ulcers can develop as a complication of avascular fibrotic or damaged thinned skin and are very common at sites of trauma, such as over the digital metacarpophalangeal or proximal interphalangeal joints or at the tip of the elbows, particularly when joint contractures are present at these sites (see [Figure 84-5](#)). Ulcerations may be noted secondary to underlying vascular disease and tissue ischemia (see vascular disease section). Ankle or lower extremity ulcers occur rarely secondary to macrovascular occlusive disease or comorbid conditions (venous disease). Hypopigmentation (vitiligo-like) and/or hyperpigmentation of the skin (“salt-and-pepper” appearance) can develop typically on the face, arms, and trunk ([Figure 84-9A](#)). General tanning of the skin may be seen, even in the absence of sun exposure.

Active skin involvement might persist for the first 12 to 18 months of the disease, with no further clinical signs of inflammation or progressive skin fibrosis seen after this interval. During this later stage, the skin begins to repair and can return to normal texture or, in areas most severely affected (e.g., fingers, hands), can become thin and atrophic. During this recovery phase, new robust hair growth is seen, particularly on the forearms, and itching and pain disappear, consistent with spontaneous resolution of disease activity. After years from disease onset, the skin rarely relapses again into an active phase and gradually can recover normal texture and color. Patients who established over time their phenotype as limited to the fingers (plus or minus facial changes) do not convert to the diffuse form of the disease.

Telangiectasias are erythematous matted skin lesions of vascular origin; for this reason, they blanch on local pressure. They are composed of vasodilated postcapillary venules without evidence of inflammation and resemble the type of lesions seen in Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Telangiectasias develop primarily on the fingers, hands, face, and mucous membranes, but they may also be found on the limbs and trunk ([Figure 84-9B](#)). They tend to become more numerous over time in both limited and diffuse types of skin disease, and are more obvious in white patients with limited scleroderma. The biologic mechanism leading to the development of telangiectasias in scleroderma is thought to be related to the underlying chronic tissue hypoxia that stimulates abnormal secretion of vascular growth factors (e.g., vascular endothelial growth factor [VEGF]). Thus, the development of telangiectasias may indicate ongoing vascular injury and abnormal vascular repair or angiogenesis. The total burden

Figure 84-9 Skin manifestations in scleroderma patients. **A**, Vitiligo-like (“salt and pepper”) discoloration of the forehead. **B**, Large facial telangiectasias.

of telangiectasias is associated with increased risk of pulmonary hypertension, suggesting that they are clinical biomarkers of systemic vascular disease. Nail-fold capillary abnormalities can be observed after immersion oil is applied to the skin surface at the base of the fingernails, and direct visualization is performed using an ophthalmoscope or by videocapillaroscopy. In early scleroderma, dilated capillary loops (giant capillaries) and microhemorrhages may be seen. At later stages, the nail-fold capillaries are attenuated and disorganized (see section on vascular changes).

Despite evidence of active inflammation during the early edematous phase of scleroderma skin involvement, systemic corticosteroids do not appear to be effective in stopping disease progression. A variety of other immunomodulatory drugs and newer agents with potential “disease-modifying properties” (i.e., antifibrotic) have been used to control the skin disease, but to date, none has proved uniformly successful (see treatment section). In the early active stage of diffuse scleroderma, pruritus can be one of the most distressing symptoms. Antihistamines, analgesics, or tricyclic antidepressants (e.g., doxepin) are often used but usually provide only partial benefit. Dryness of the skin surface results from damage to the exocrine structures caused by decreased or absent natural oil (sebum) production. This can worsen

pruritus, leading to skin trauma due to repetitive scratching. Ulceration and secondary tissue infection may also result. The best approach to treatment is characterized by frequent topical application of an emollient preparation, periodic cleansing with soap and water, and use of topical antibiotics for any traumatic skin ulceration. Physical therapy is most important to prevent severe skin and joint contractures, and to help patients with activities of daily living.

GASTROINTESTINAL INVOLVEMENT

KEY POINTS

Manifestations of gut dysmotility are universally present in scleroderma and can affect any segment of the gastrointestinal tract.

Involvement of the upper GI tract is more common and can present with severe symptoms.

Dysfunction and failure of the lower GI tract are associated with poor prognosis.

Almost every scleroderma patient has symptoms of gastrointestinal disease, ranging from mild gastroesophageal reflux disease (GERD) to severe bowel dysfunction, which can be life threatening. Virtually any segment of the gastrointestinal tract can be affected (Table 84-4).

Oropharynx

Patients may report that chewing is difficult because of decreased facial flexibility caused by skin and deeper tissue fibrosis. Perioral skin tightening can result in a decreased oral aperture and inability to open the mouth wide enough

for proper dental care or to bite into large solid foods such as an apple (Figure 84-10). Dry membranes resulting from decreased saliva production can lead to difficult mastication. In some patients, periodontal disease and gum regression cause loosening of teeth, which further affects chewing capacity.

Upper pharyngeal function is usually normal, but a subset of patients may develop a myopathy that causes weakness of pharyngeal muscles, mimicking a neuromuscular disease.⁶⁴ This manifestation is characterized by pharyngeal dysfunction with problems initiating swallowing and frequent coughing due to laryngeal penetration and can be associated with increased risk for aspiration of foods or liquids. Although limited pathologic studies of the upper pharyngeal structures have examined scleroderma, both myositis and fibrosis are known to occur.

Esophagus

Dysphagia resulting from esophageal disease is the most common gastrointestinal symptom, occurring in approximately 90% of patients. Heartburn, regurgitation, and dysphagia for pills and solids (more than liquids) are the most common symptoms, but atypical retrosternal pain (particularly at night), periodic cough, a sense of food “sticking” in the esophagus, and nausea can result from esophageal dysfunction. Esophageal involvement in scleroderma is characterized by loss of normal smooth muscle function, especially in the lower two-thirds of the esophagus, and hypotonia of the lower esophageal sphincter (Figure 84-11A). Functional studies of esophageal motility suggest that neural dysfunction is common in patients with scleroderma, and that this may precede myopathic dysfunction and histologic changes in smooth muscle layers.⁶⁵ Manometric evaluation has identified the presence of esophageal hypomotility in areas that later did not show any histologic

Table 84-4 Gastrointestinal Manifestations of Scleroderma

Site	Manifestation	Management
Oropharynx	Perioral tight skin Decreased oral aperture Periodontitis, gum disease Dry mouth Swallowing difficulties	Regular dental and periodontal care Artificial saliva Targeted swallowing exercises and rehabilitation
Esophagus	Coughing, aspiration Acid reflux (heartburn) Dysphagia	Lifestyle modifications Proton pump inhibitors Prokinetics Upper gastrointestinal endoscopy
Stomach	Strictures Barrett's esophagus Gastroparesis, dyspepsia Gastric antral vascular ectasia	Prokinetics Proton pump inhibitors, iron replacement Endoscopic laser or cryotherapy Transfusions Surgery
Small and large intestine	Hypomotility, constipation Bacterial overgrowth, diarrhea Pseudo-obstruction Pneumatosis intestinalis Malabsorption Colonic pseudodiverticula	Mild laxatives Promotility agents Rotational antibiotics Octreotide Avoidance of surgery Enteral or parenteral nutrition support
Anorectum	Sphincter incompetence	Biofeedback, sacral nerve stimulation, surgery

Figure 84-10 Oral manifestations. **A**, Perioral skin tightening with decreased oral aperture, furrowing around the lips, and dry membranes. **B**, Periodontal disease with regression of gum and loosening of teeth. **C** and **D**, Telangiectasias on lips and tongue.

abnormality of the smooth muscle. Other studies have shown esophageal smooth muscle activity in response to pharmacologic stimulation (methacholine challenge) early in the disease, but not in patients with more advanced scleroderma. The cause of these abnormalities is unknown, but clear evidence indicates that neural dysfunction precedes muscle disease.

Tissue fibrosis is often evoked as the cause of esophageal disease in scleroderma. However, pathologic studies demonstrate atrophy of the smooth muscle layers of the distal esophagus in the absence of significant fibrosis. Ischemia of the esophagus in scleroderma is suggested by functional studies that show impaired esophageal blood flow following cold exposure and rewarming protocols. Noninflammatory intimal layer hyperplasia in arterioles of the gastrointestinal tract has been described. Inflammatory infiltrates usually are not present in the smooth muscle unless severe transmural esophagitis is present. This suggests that inflammation is not a cardinal feature of the pathogenesis of esophageal smooth muscle lesions in scleroderma.

The severity of esophageal symptoms may not accurately reflect the seriousness of the underlying disease. Therefore, every patient with scleroderma should be fully evaluated for esophageal involvement. If untreated, gastrointestinal reflux may lead to esophagitis, bleeding, esophageal strictures, or precancerous lesions such as Barrett's esophagus. The asymptomatic patient without abnormal laboratory testing

(anemia, positive evidence of gastrointestinal bleeding) does not require specific interventions. Patients with mild GERD can be treated empirically with proton pump inhibitors and then can be followed clinically if they become symptom free with normal laboratory data. When more severe symptoms are present (e.g., GERD with dysphagia), or when treatment with proton pump inhibitors fails, an upper gastrointestinal endoscopy is necessary to fully assess the anatomy of the esophagus and the extent of related disease. Direct endoscopy is appropriate to rule out Barrett's esophagus, stricture, or a site of uncontrolled esophagitis or bleeding. Barium swallow and cine-esophagography are sensitive tests for esophageal strictures. However, direct measurement of esophageal motility via esophageal manometry may be needed if the cause of symptoms such as atypical chest pain is unclear. Although complications from Barrett's esophagus (e.g., esophageal cancer) are uncommon, periodic re-endoscopy to reassess status is recommended, even if symptoms are under therapeutic control.

It is critical that patients alter eating behavior to complement medication therapy. Patients often do better by eating more frequent smaller meals, avoiding food intake for several hours before bedtime, moving the main meal toward mid-day, taking a walk after meals to help gastroesophageal emptying, and eliminating foods that aggravate symptoms (e.g., spicy sauces, caffeinated or carbonated beverages). Bedtime is often the time of severe reflux. This can be

Figure 84-11 Gastrointestinal manifestations in scleroderma. **A**, Chest computed tomography (CT) (sagittal view) showing severe esophageal dysmotility with dilation and (arrow) retention of gastric content. **B**, Upper endoscopy: gastric antral vascular ectasias presenting as “watermelon” stomach. **C** and **D**, Plain abdominal x-ray and abdominal CT: small intestinal dysmotility with pseudo-obstruction, pneumatosis cystoides intestinalis.

improved by avoiding filling the stomach at least 2 to 3 hours before bedtime and by elevating the head and trunk during sleep. Treatment of reflux by suppression of gastric acid with antacids or histamine-2 (H_2)- is helpful but overall disappointing in scleroderma. Conversely, proton pump inhibitors (e.g., omeprazole, lansoprazole) can be very effective. Usually, long-term daily use is required. Higher doses may be used periodically for breakthrough symptoms. If symptoms are not controlled with recommended medication dosages, then a formal 24-hour ambulatory pH study may be necessary to determine whether persistent symptoms are due to uncontrolled acid reflux. A prokinetic drug (e.g.,

metoclopramide, domperidone, erythromycin) should be added when symptoms of dysphagia or endoscopic findings of esophagitis are present despite the use of effective acid suppression. These medications tend to be effective during early disease but are less likely to help later on, with advanced esophageal dysfunction. Long-term use of prokinetics may be needed. Many patients respond to relatively low doses, for example, at bedtime alone. Given the increased risk of neurologic complications with the use of metoclopramide, many recommend domperidone as a relatively safer alternative when long-term prokinetic treatment is needed.

Stomach

The degree of delayed gastric emptying (gastroparesis) is underappreciated in scleroderma, and gastroparesis often causes early satiety, aggravation of GERD symptoms, anorexia, abdominal pain, a sensation of bloating, or nausea. Frequently, weight loss in scleroderma patients is a consequence of poor caloric intake due to lack of appetite from poor gastric function. Prokinetics are used to improve gastric emptying and related symptoms. Gastritis or gastric ulcer can occur. Dilation of the microvasculature in the gastric mucosa is found in a subset of patients. This manifestation, also called *gastric antral vascular ectasia* (GAVE), is thought to be caused by an abnormal angiogenesis, leading to bizarre dilation of microvessels and arterial-venous (A-V) malformations similar to the telangiectasias seen in the skin, lips, and oral mucous membranes. In general, these lesions are asymptomatic, but they can be responsible for occult gastrointestinal bleeding. Extensive clusters of A-V malformations lead to the presence of longitudinal red stripes in the inner lining of the stomach, converging to the pylorus and described on endoscopy as “watermelon stomach,” based on their appearance (Figure 84-11B). Endoscopic therapy with laser photocoagulation or cryotherapy can be used to ablate bleeding vessels. Rarely, bleeding associated with GAVE is refractory and requires multiple transfusions, repeated laser or cryotherapy, or even gastric surgery (e.g., antral or gastric resection).

Lower Gastrointestinal Tract

Bloating, abdominal distention, diarrhea, and constipation are common complaints caused by dysmotility of the small and large bowel. Functional and pathologic studies again suggest that microvascular disease, neural dysfunction, smooth muscle atrophy, and tissue fibrosis similar to those seen in the esophagus are causing the bowel disease. Most cases present in similar fashion to irritable bowel syndrome (IBS). Constipation due to sluggish or atonic bowel function can result in repeated bouts of diarrhea with malabsorption, progressive loss of weight, and severe malnutrition. Diarrhea is thought to be caused by bacterial overgrowth as a consequence of bowel dysfunction, but other causes have been considered, including decreased mesenteric blood flow or pancreatic insufficiency. Recurrent episodes of pseudo-obstruction constitute one of the most serious intestinal problems in scleroderma. These episodes are sometimes mistaken for surgical emergencies. Pseudo-obstruction is a manifestation of profound loss of bowel smooth muscle function, causing severe dysmotility and segments of luminal dilation. Pneumatosis cystoides intestinalis sometimes complicates scleroderma of the bowel when gas leaks into the diseased intestinal wall and tracks into the mesentery of the gut or the peritoneal cavity, mimicking a bowel perforation (Figure 84-11C and D). Asymptomatic wide-mouthed diverticula, also resulting from fibrosis and atrophy of the bowel wall, are pathognomonic of scleroderma. Volvulus, stricture, and perforation are uncommon complications of severe bowel involvement.

Management of the lower gastrointestinal tract includes avoiding a constipation-diarrhea cycle through adequate fiber ingestion, use of stool softener (docusate), or, if

constipation is severe, periodic doses of osmotic laxatives (polyethylene glycol). Lubiprostone is helpful if chronic constipation predominates. Other prokinetic drugs are less effective for treatment of the lower gastrointestinal tract. Octreotide is reported to help patients with severe lower GI hypomotility and pseudo-obstruction. In cases with bloating, recurrent bouts of diarrhea, or episodes of pseudo-obstruction, the use of cyclic antibiotics and/or probiotics is helpful. Total parenteral nutrition may become necessary in patients with severe scleroderma-related bowel disease without response to other medical therapy. The presence of intestinal failure is a poor prognostic complication. Fecal incontinence can result in scleroderma caused by dysfunction of both internal (atrophy and fibrosis) and external (weakness) anal sphincters. Successful treatment includes firming stool texture, performing exercises to strengthen the pelvic muscles, providing biofeedback methods, and conducting surgical repair of aggravating factors such as rectal prolapse or severe hemorrhoids.

PULMONARY INVOLVEMENT

Pulmonary involvement is found in most scleroderma patients. Interstitial lung disease and pulmonary hypertension are recognized as the most common lung complications and now are regarded as the major cause of death in scleroderma. In combination, it is estimated that they are responsible for 60% of scleroderma-related deaths.¹⁸ They are present in many patients at the same time, but one process may dominate over the other. Lung disease can occur without symptoms, or it can cause progressive respiratory failure and severe limitation of the quality of life. Additional pulmonary complications such as chronic aspiration, pleural disease, spontaneous pneumothorax, neuromuscular weakness, drug-induced pneumonitis, and lung cancer need to be considered in the differential diagnosis of a scleroderma patient presenting with respiratory symptoms.

Interstitial Lung Disease

KEY POINTS

Lung disease is a major cause of morbidity and mortality in scleroderma patients.

Pulmonary fibrosis occurs in both limited and diffuse subsets of scleroderma, with a variable disease course in terms of severity and outcome.

Nonwhite and antitopoisomerase 1–positive patients generally have the worst prognosis.

Pulmonary function testing (spirometry and diffusing capacity) is helpful for screening and monitoring of interstitial lung disease (ILD). The degree of lung fibrosis on high-resolution computed tomography (HRCT) predicts outcome.

Treatment for scleroderma-related ILD is limited to immunosuppression.

Risk factors for pulmonary arterial hypertension include late onset of scleroderma, limited phenotype, presence of numerous telangiectasias, and positive anticentromere antibodies.

Interstitial lung disease (ILD) is the most common lung manifestation, occurring to some degree in about 80% of patients with diffuse cutaneous scleroderma and in 20% of patients with limited skin disease. Higher risk to develop severe progressive ILD has been observed in patients with diffuse skin involvement, African-Americans, Native Americans, and those positive for antitopoisomerase 1 (Scl-70), anti-U3-RNP, or anti-Th/To antibodies. Data from a recent study of patients with active lung disease show that patients with limited and those with diffuse scleroderma were indistinguishable with regard to their baseline pulmonary functions, although patients with limited skin disease presented with more extensive pulmonary fibrosis, perhaps reflecting a delay in diagnosis and more advanced progression of lung disease before study entry.⁶⁶

ILD typically manifests with declining lung volumes and increased parenchymal fibrosis with reticular interstitial thickening that is greatest at the lung bases. Pathologic studies have shown that the most common histologic pattern of fibrosing alveolitis in scleroderma is nonspecific interstitial pneumonia (NSIP), as opposed to usual interstitial pneumonia (UIP), which is instead the common presentation of idiopathic pulmonary fibrosis. A mixed pattern of NSIP and UIP can also be found. The histopathologic classification does not appear to predict outcome, which is more related to baseline disease severity and functional respiratory measures.⁶⁷ For this reason, a surgical lung biopsy is not required in the setting of scleroderma patients who are following a typical disease course. Although ILD is

usually characterized by a functional restrictive ventilatory defect with reduced gas exchange, at later stages of the disease some degree of airway obstruction can be found in association with honeycombing of lung parenchyma and bronchiectasis. Pleural reactions are not common in scleroderma. Rare cases of spontaneous pneumothorax, adult respiratory distress syndrome, and pulmonary hemorrhage have been reported. Aspiration secondary to gastroesophageal reflux disease (GERD), secondary infection, and heart failure can complicate the course of scleroderma lung disease. Some authors consider GERD associated with chronic aspiration a potential inciting factor for the development of ILD in scleroderma.⁶⁸

During earlier stages of ILD, the underlying active fibrosing alveolitis may be totally asymptomatic and may not be detected by conventional chest radiographs. The most common symptoms of scleroderma lung disease are dyspnea (initially on exertion) and fatigue. Chest pain is not typical, and nonproductive cough is usually a late complication, particularly in association with the presence of traction bronchiectasis. Coughing in scleroderma often is not a primary lung problem but rather is a manifestation of GERD with associated laryngeal irritation. The most characteristic finding of ILD on physical examination is bilateral fine inspiratory crackles (i.e., “velcro” rales) at the lung bases. Pulmonary function testing (PFT) is the method most commonly used to detect interstitial lung disease (Figure 84-12). The earliest functional abnormality is a reduction in the single breath diffusion capacity of carbon monoxide

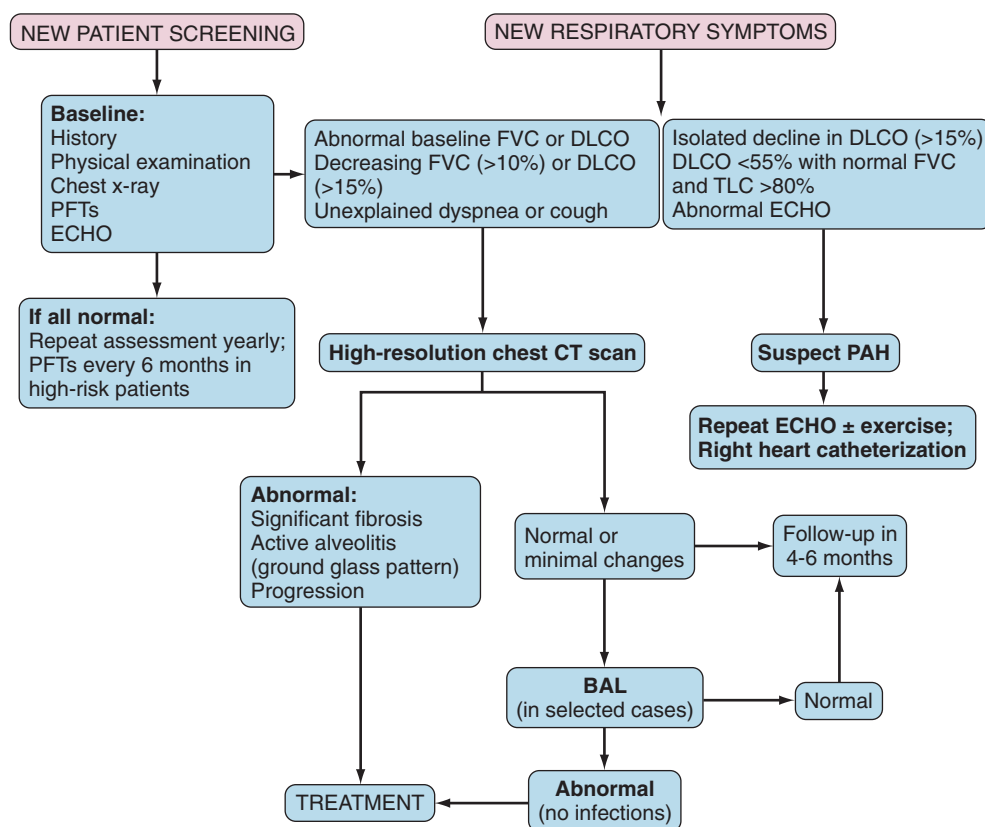

Figure 84-12 Approach to lung disease in scleroderma. This approach is recommended for all patients with scleroderma with both new-onset and long-standing disease. BAL, bronchoalveolar lavage; CT, computed tomography; DLCO, diffusing capacity; ECHO, echocardiography; FVC, forced vital capacity; PAH, pulmonary arterial hypertension; PFT, pulmonary function test; TLC, total lung capacity.

(DLCO). Although a decline in DLCO correlates with the severity of pulmonary fibrosis as measured by HRCT and predicts worse outcome, it is not a very specific measure and can be abnormal also in the context of pulmonary vascular disease and underlying chronic obstructive disease/emphysema. A restrictive ventilatory defect is identified by a depression of the forced vital capacity (FVC) and the total lung capacity (TLC). Serial measurements of FVC are the most reliable tool with which to follow ILD. A decline in FVC of more than 10% from baseline is often indicative of disease activity and is associated with increased mortality. Lung function may remain stable after an initial decline at disease onset, or it can progress at 4- to 6-month intervals until severe disease develops after a few years. Patients presenting with a normal FVC during early stages of scleroderma have a better lung prognosis, and an early reduction in FVC is likely to be associated with further progression of lung involvement, usually within the first 2 to 3 years from disease onset. The presence of ILD predicts increased mortality. One study found that patients with severe ILD have a 9-year survival rate of approximately 30%, whereas patients with no severe organ involvement have a 72% survival rate.¹⁸ The most rapid decline in FVC is thought to occur within the initial 3 years from disease onset, but progression of ILD can occur in later years, so it is recommended that respiratory status be monitored on a regular basis, and that pulmonary function be tested yearly.

High-resolution computed tomography (HRCT) is more accurate than chest radiography in evaluating diffuse lung disease; it is a well-established, sensitive, and noninvasive method of detecting and characterizing ILD in scleroderma. The extent of pulmonary fibrosis on HRCT correlates closely with PFT abnormalities and can be used to predict prognosis.⁶⁹ Recent evidence shows that the degree of HRCT changes coupled with the level of lung function deficit can be used to generate a simple staging system (limited vs. extensive disease) with good prognostic value.⁷⁰ An FVC of less than 70% or a disease extent on HRCT greater than 20% predicts ILD progression and higher mortality. HRCT features of fibrosis are present in 55% to 65% of all patients with scleroderma and in almost every patient with abnormal pulmonary function tests. The earliest and most common abnormality on HRCT is usually found in the posterior and basilar portion of the lungs in the form of increased subpleural lung attenuations in the absence of distinct architectural distortion. With progression of the disease, increased “ground glass” opacities (GGO) are seen, but it has been well established that these changes alone are not always indicative of active inflammation, nor can they predict progression itself. Subsequent detection of a fine reticular pattern often precedes overt pulmonary fibrosis manifested by parenchymal distortion, reticular intralobular interstitial thickening, traction bronchiectasis and bronchiolectasis, and, in the late stages, honeycomb and cystic air spaces (Figure 84-13). When reticular interstitial abnormalities are present on HRCT, regression of disease rarely, if ever, occurs.

Pathologic studies on scleroderma patients with early lung disease have shown that lung fibrosis is preceded by the presence of a mixed interstitial inflammatory infiltrate spilling into the alveolar spaces (alveolitis). It has been assumed that measuring abnormal levels of inflammatory

cells in the bronchoalveolar lavage (BAL) would have allowed identification of patients with active lung disease at risk for progression and with potential benefit from immunosuppressive therapy. Published data have shown that an abnormal BAL cell count, in particular with increased granulocytes (neutrophils and eosinophils), is associated with more severe lung disease and mortality in patients with scleroderma ILD.⁷¹ However, the value of BAL cytology in predicting lung disease progression or response to treatment has not been uniformly confirmed. Few observational studies have indicated that the presence of BAL granulocytic alveolitis was associated with significant deterioration of lung function tests over time in patients not receiving immunosuppressive therapy.⁷² In contrast, other studies did not find a clear association between BAL cellular abnormalities and clinical outcomes.⁷³ At present, evidence to recommend routine clinical use of BAL cytology to predict outcome in patients with scleroderma and ILD is still insufficient.

Early detection and prompt therapeutic intervention remain essential in preventing progression of lung disease. Current treatment of scleroderma-related ILD is most often directed against the immune response and the inflammatory process mediating lung injury and tissue fibrosis. A randomized placebo-controlled study comparing 1 year of oral cyclophosphamide versus placebo suggests some modest benefit of the active drug (improvement in FVC).⁶⁶ This benefit was sustained at 18 months but was completely lost after 2 years' follow-up, suggesting that a sequential or maintenance immunosuppressive approach may be indicated to retain the clinical response. Other studies suggest benefit using intravenous monthly cyclophosphamide followed by azathioprine as maintenance therapy. Several small retrospective studies have shown moderate benefit from mycophenolate mofetil (MMF) with improvement in or stabilization of lung function, suggesting that this drug may prove to be a safe and effective treatment in scleroderma patients, and a possible alternative to cyclophosphamide. Although more studies are needed to confirm the benefit of immunosuppressive therapy in scleroderma-associated ILD, newer drugs are under investigation, including targeted biologic immunotherapies and antifibrotic molecules (see general therapy section). More aggressive immunosuppressive protocols such as autologous or allogeneic hematopoietic stem cell transplantation, preceded by myeloablative or immunoablative conditioning regimens, are under investigation, but their treatment toxicity remains a concern.

It remains very important to pursue careful selection of patients and to treat only those with evidence of active lung disease. In fact, in most cases, no or minimal progression to severe disease is seen despite some evidence of underlying pulmonary fibrosis. This is best done with serial studies and careful assessment of both pulmonary function tests and HRCT scans.

Lung transplantation is an option in patients with severe ILD not responsive to medical therapy. Carefully selected scleroderma patients undergoing lung transplantation have similar morbidity and mortality as patients undergoing transplantation for idiopathic lung disease.⁷⁴ A retrospective survey of 47 scleroderma patients who underwent lung transplantation found that 1- and 3-year survival rates were 68% and 46%, respectively.

Pulmonary Hypertension

Pulmonary arterial vascular disease is a common manifestation of scleroderma; when associated with pulmonary arterial hypertension (PAH), it represents a difficult clinical challenge with life-threatening consequences. The pulmonary vascular process can be indolent and remain clinically silent, or it may lead to respiratory distress secondary to severe PAH and associated right heart failure. Typical symptoms associated with clinically manifested PAH include dyspnea on exertion, fatigue, and, less commonly, chest pain or syncope. Physical examination may be normal during early stages of PAH, but as the disease progresses, a systolic murmur of tricuspid regurgitation, a loud pulmonic component, the S2, an S3 gallop, and signs of right heart failure

(right-sided parasternal heave, prominent and elevated jugular venous pulse, hepatomegaly, signs of fluid overload with peripheral edema) are seen. Later in the disease, patients become dyspneic with little activity, have a resting tachycardia, and may appear cyanotic. Sudden syncope or death can occur owing to hypoxia and congestive heart failure.

PAH is usually a late complication of scleroderma, typically manifesting after 10 years from disease onset, particularly in patients with limited cutaneous involvement. Considering the potentially devastating consequences of PAH, early diagnosis is very important. Simple bedside examination is not very sensitive, particularly during early stages; thus it is recommended to screen every scleroderma patient using objective testing such as electrocardiography

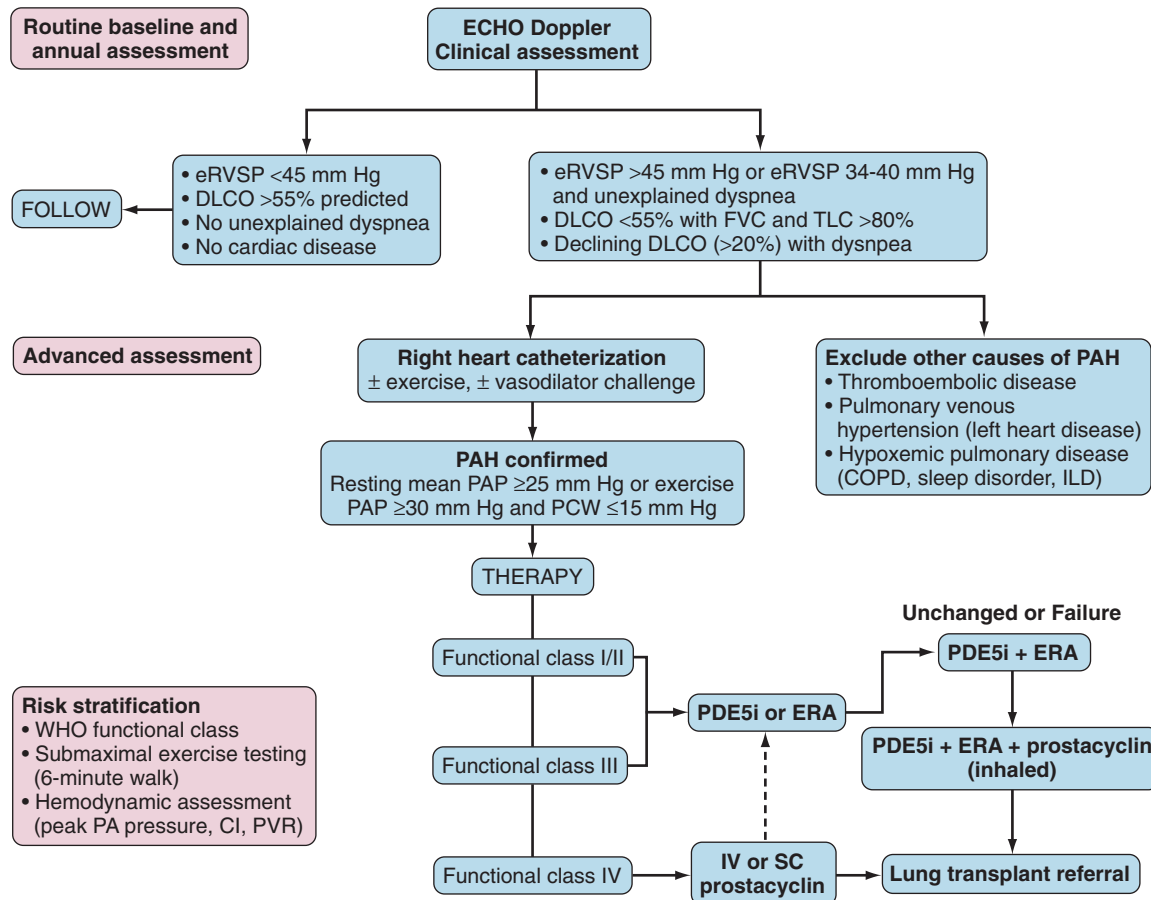

Figure 84-14 Approach to scleroderma-associated pulmonary arterial hypertension (PAH). This approach is recommended for all scleroderma patients with new-onset disease or especially long-standing disease with limited scleroderma. CI, cardiac index; COPD, chronic obstructive pulmonary disease; DLCO, diffusing capacity; ECHO, echocardiography; ERA, endothelin receptor antagonist; eRVSP, estimated right ventricular systolic pressure; FVC, forced vital capacity; ILD, interstitial lung disease; IV, intravenous; PA, pulmonary artery systolic pressure; PAP, pulmonary artery pressure; PCW, capillary wedge pressure; PDE5i, phosphodiesterase-5 inhibitor; PVR, pulmonary vascular resistance; SC, subcutaneous; TLC, total lung capacity on pulmonary function testing. Functional class: World Health Organization (WHO) functional classification of disease severity in PAH according to level of function and associated symptoms. Increasing WHO functional class reflects more severe symptoms and greater restriction in activity.

(ECG), echocardiography (ECHO), and pulmonary function testing (Figure 84-14). The ECG can be normal, but as disease progresses, signs of right-sided heart strain with right ventricular hypertrophy and right axis deviation can be observed. Detection by ECHO of increased right ventricular systolic pressure (RVSP) is useful, but values need to be confirmed by right heart catheterization (RHC), given the possibility of false-positive or false-negative results. When the ECHO estimates an RVSP greater than 45 mm Hg, about 95% of the time this will be confirmed by RHC.⁷⁵ Some use the tricuspid gradient (TG) as a measure of pulmonary artery pressure. Additional noninvasive screening includes pulmonary function testing. A low diffusing capacity (DLCO) without evidence of obstructive or restrictive lung disease (low forced vital capacity, or FVC) suggests a defect in gas exchange secondary to pulmonary vascular disease or PAH. DLCO may progressively decline for years before the diagnosis of PAH is established.⁷⁶ Increased serum N-terminal pro-brain natriuretic peptide (NT-proBNP) may indicate the presence of PAH and right heart strain, even when levels are modestly elevated (>395 pg/mL).⁷⁷ The diagnosis of PAH should be confirmed by RHC, providing direct measurement of pulmonary

hemodynamics. PAH is defined as resting mean pulmonary arterial pressure equal to or greater than 25 mm Hg, with normal pulmonary capillary wedge pressure equal to or less than 15 mm Hg. In addition to confirming abnormal hemodynamic values, the RHC can help in differentiating true PAH from pulmonary venous hypertension secondary to left heart failure or pulmonary occlusive disease. The 6-minute walk test can provide baseline functional information but cannot accurately assess the severity of PAH. Because in scleroderma patients, baseline hemodynamic parameters do not correlate well with the clinical course of PAH, new cardiopulmonary dynamic testing such as exercise stress ECHO and exercise during RHC have been introduced, but their role in diagnosing or monitoring PAH has not yet been fully established.

Based on the definition and the tools used to obtain measurements, the prevalence of PAH in scleroderma has been reported with variability. Using ECHO as a diagnostic tool, the prevalence of PAH has been estimated at between 30% and 50% of all studied patients, and investigations using confirmatory RHC have detected a prevalence of 8% to 12%.^{78,79} Clinically, scleroderma-related pulmonary vascular disease can present in three different ways. In some

patients, it manifests and progresses as severe isolated PAH in the absence of other significant lung disease. In others, it can be associated with mild or severe pulmonary fibrosis that is believed to drive vascular disease and PAH by causing chronic hypoxia coupled with destruction of lung parenchyma and underlying vasculature. Association of ILD and PAH usually entails a worse prognosis. In a third group of patients, pulmonary vascular disease presents with dyspnea on exertion, isolated decline of the DLCO with no significant signs of ILD (i.e., low lung volumes), and a normal resting ECHO and/or RHC. These patients are considered to have microvascular lung disease and may be at high risk to develop overt PAH. Increased risk of developing PAH has been associated with limited skin disease, late age at onset of scleroderma, presence of numerous telangiectasias, low DLCO, and presence of anti-U3-RNP antibody. Some studies suggest that the presence of anticentromere, anti-B23, and anti- β_2 -glycoprotein I antibodies also increases the risk for PAH.

PAH has a major impact on quality of life and survival of affected patients. The natural course of the disease is characterized by progression of hemodynamic impairment, resulting in right heart failure and leading to a poor outcome. Despite the availability of newer targeted therapies, the median survival in scleroderma patients with PAH ranges between 1 and 3 years.^{80,81} A progressive rapid increase in pulmonary pressure is more likely to occur in patients with limited skin disease and late age at onset of scleroderma.⁸² This more aggressive course is associated with high mortality. Survival in patients with ILD-associated PAH is significantly worse (3-year survival, 46%) than in those with PAH alone (3-year survival, 64%).⁸³ This difference is possibly explained by the presence in scleroderma of underlying comorbidities, and in particular of biventricular heart (myocardial) involvement. A 10-fold increase in NT-proBNP blood levels is associated with higher mortality.^{84,85} ECHO findings can help predict prognosis. For example, the degree of tricuspid annular plane systolic excursion (TAPSE) reflects right ventricular function. A TAPSE of less than 1.8 cm is associated with decreased survival in patients with PAH.⁸⁶ A recent survey identified that pulmonary vascular resistance, stroke volume index, and pulmonary arterial capacitance were strong predictors of survival.⁸⁷ This suggests that right ventricular dysfunction is associated with poorer outcome. Male gender and higher New York Heart Association functional class also impact prognosis negatively. It is suggested that survival has improved with current modes of therapy. One survey found 47% 2-year survival in historical controls as opposed with 71% among patients treated with modern therapy.⁸⁸

All patients with PAH are encouraged to continue an active lifestyle as tolerated. Formal educational and exercise programs can improve their quality of life. Conventional therapy includes diuretic therapy (loop and potassium-sparing diuretics) and supplemental oxygen therapy if needed. Anticoagulation is used if there is no defined risk for bleeding. Although calcium channel blockers may help patients with evidence of acute vasodilative response during hemodynamic testing, this is an uncommon finding in scleroderma. In recent years, a number of targeted agents have become available for the treatment of PAH. Many clinical trials testing these drugs in primary PAH have

included about 20% of patients with connective tissue disease, primarily scleroderma. Specific therapies include prostaglandin derivatives (epoprostenol, treprostinil, beraprost, iloprost), endothelin receptor antagonists (bosentan, sitaxsentan, ambrisentan), and phosphodiesterase-5 inhibitors (sildenafil, tadalafil, vardenafil). These interventions can improve hemodynamics, exercise tolerance, and quality of life. No evidence from clinical trials suggests that any one of these agents is superior to another. Most believe that early intervention is most important, and that combination therapy may be helpful (see [Figure 84-14](#)). Decisions regarding the preferred agents to use and how to deliver them are based mostly on personal preferences and the clinical status of the individual patient. For patients with mild to moderate disease (functional class I or II), a single oral agent is usually started (i.e., sildenafil, bosentan, ambrisentan). Our preference is to use sildenafil, given its favorable side effect profile. Patients presenting with more severe disease (class III or IV) and those failing monotherapy are usually treated with intravenous or inhaled prostaglandins alone or in combination with one or two oral agents. Sildenafil and bosentan can be used in combination, even if concern arises about their interaction and increased hepatotoxicity.^{89,90} Lung or heart-lung transplantation for PAH remains the treatment of last resort when medical therapy fails. Patients with scleroderma who are carefully selected for transplantation have an outcome that is similar to those with other causes of lung disease. PAH in scleroderma is a progressive disease for which no specific or single therapy may suffice. Therefore, careful longitudinal monitoring is important. Noninvasive testing with periodic clinical assessment with 6-minute walk time, repeat pulmonary function testing, and ECHO studies are helpful. When a major therapeutic decision is needed, such as switching or adding a new therapy, a repeat RHC may be indicated. Further improvement in survival of scleroderma patients with PAH may result from future therapeutic interventions targeting the underlying inflammatory process and the dysregulated endothelial proliferation mediating pulmonary vascular remodeling and consequent failure of the right heart.

CARDIAC INVOLVEMENT

The clinical manifestations of heart disease in scleroderma are highly variable, ranging from clinically silent cardiac involvement to frank heart failure. The reported prevalence of heart disease varies from 10% to more than 50%, depending on the diagnostic method used, but in general it tends to be underestimated. Symptoms such as dyspnea, chest pain, or palpitations are commonly thought to be secondary to more obvious organ involvement such as the lungs or the upper gastrointestinal tract, and the contribution of heart disease often is not appreciated until later stages. Cardiac disease can occur in both diffuse and limited subtypes of scleroderma and can manifest as a primary heart problem or in association with other organ failure. When clinically evident, heart disease entails an overall poor prognosis and predicts shortened survival.⁹¹ Along with pulmonary fibrosis and PAH, cardiac disease accounts for the majority of deaths in scleroderma. One study found that 25% of deaths could be directly related to heart disease (mostly heart

failure and arrhythmias).¹⁶ In a large meta-analysis, cardiac involvement was associated with increased mortality (hazard ratio, 2.8; 95% confidence interval [CI], 2.1 to 3.8) after adjustments for age and gender.⁹² A survey comparing 129 scleroderma patients with a left ventricle ejection fraction (LVEF) of less than 55% with 256 subjects with normal LVEF demonstrated that male gender, age, digital ulcerations, myositis, and no use of calcium channel blockers were independent factors associated with left ventricular dysfunction.⁹³

Cardiac disease in scleroderma can be characterized by involvement of the endocardium, myocardium, and pericardium, separately or concomitantly. As a consequence, pericardial effusion, auricular and/or ventricular arrhythmias, conduction disease, valvular regurgitation, myocardial ischemia, myocardial hypertrophy, and heart failure are all reported. Clinically overt pericarditis is uncommon, but asymptomatic and hemodynamically benign pericardial effusions are frequently detected by ECHO. In a controlled study, significant pericardial effusion was found in about 15% of patients compared with 4% of controls.⁹⁴ Pathologic studies have shown that some degree of pericardial involvement is detectable in 33% to 77% of scleroderma patients, usually with evidence of a fibrinous pericarditis with adhesions and chronic inflammatory cell infiltrates.⁹⁵ Hemodynamic compromise secondary to tamponade physiology is rare but may require acute intervention with anti-inflammatory medication, pericardiocentesis, or creation of a pericardial window for slow decompression. The presence of a large pericardial effusion even if asymptomatic is a poor prognostic sign, particularly if associated with PAH or renal disease.

Focal myocardial fibrosis is the hallmark of established primary heart involvement in SSc and usually is not secondary to atherosclerotic coronary artery disease. In fact, pathologic studies and a survey of coronary angiograms have found little involvement of coronary arteries in scleroderma patients.^{7,96} Unlike other rheumatic diseases such as rheumatoid arthritis or SLE, scleroderma does not exhibit unequivocally an increased risk for coronary artery disease independent from usual risk factors. Nevertheless, typical angina symptoms should make one consider atherosclerosis of the coronary vessels or another process. Atypical chest pain can also be caused by musculoskeletal problems, esophageal reflux disease, or PAH mimicking cardiac disease. The fibrotic lesions in the heart of scleroderma patients are patchy, involve the myocardium of both ventricles, and usually are accompanied by evidence of microvascular disease with concentric intimal hypertrophy associated with fibrinoid necrosis of the intramural coronary arteries and arterioles.⁹⁷ This results in reduced coronary flow reserve even with normal epicardial coronary arteries and in the absence of clinically manifested cardiac dysfunction.⁹⁸ Vasospasm and associated myocardial perfusion defects are demonstrated to occur at rest, with exercise, and following cold exposure.⁹⁹ These findings suggest that myocardial fibrosis may be associated with reversible vasospasm of the microvascular coronary circulation, and that vasodilating agents such as calcium channel blockers may have the capacity to improve coronary flow and prevent further cardiac damage.¹⁰⁰ Patients with angina-like chest pain may need to undergo angiographic studies because nuclear perfu-

sion studies are likely to be abnormal as a result of microvascular disease.

Electrocardiography (ECG) and Holter monitoring will often show some heart conduction defect or asymptomatic arrhythmia; these are thought to be consequences of myocardial fibrosis. Premature ventricular contractions are the most common abnormality, but sinus node dysfunction, first-degree heart block, supraventricular arrhythmias (supraventricular tachycardia, atrial fibrillation), and ventricular arrhythmias (ventricular tachycardia) are also observed. Complete heart block is uncommon. Scleroderma-related syncope is an ominous manifestation of late-stage PAH or an important arrhythmia. When an arrhythmia is suspected, a Holter monitoring study should be ordered promptly. More extensive evaluation with electrophysiologic studies is indicated in serious cases because a pacemaker or ablative therapy can help in management of these life-threatening complications.

Transthoracic echocardiography (TTE) is a widely used type of noninvasive cardiac testing; it represents a sensitive tool to detect the presence of cardiac disease. TTE can provide estimates of elevated right ventricular (RV) and pulmonary artery pressures, as well as evidence of right heart dysfunction such as atrial and ventricular dilation or septal wall motion abnormalities. A depressed left ventricular (LV) contractility is not frequently detected in scleroderma patients with the use of conventional TTE, but relaxation abnormalities can be found in up to 40% of cases.¹⁰¹ Left ventricular diastolic dysfunction is detected especially in patients with diffuse scleroderma, and may occur in the absence of systemic hypertension (independent of renal disease) and in association with pulmonary vascular disease. Although TTE is very helpful in monitoring underlying cardiac abnormalities later in the disease process, it lacks some sensitivity during preclinical stages of heart involvement. Novel diagnostic methods such as tissue Doppler echocardiography (TDE), with or without strain imaging, and magnetic resonance imaging (MRI) have been applied more recently to study myocardial disease in scleroderma, showing the ability to detect abnormalities earlier than conventional echocardiography and with greater accuracy.^{102,103} Provocative exercise testing during echocardiography can be used to detect underlying diastolic dysfunction and pulmonary hypertension not previously recognized by resting studies.

Cardiac evaluation has been improved by the systematic measurement of brain natriuretic peptide (BNP) or its prohormone N-terminal pro-BNP (NT-proBNP). Blood levels of NT-proBNP reflect both RV and LV volume or pressure overload. It can be a useful test and a prognostic marker for following right or left heart failure in scleroderma patients.^{85,104}

Patients with diffuse cutaneous scleroderma and skeletal muscle inflammation (polymyositis) are particularly prone to develop severe cardiomyopathy and to have a particularly poor prognosis. Acute myocarditis can also occur in association with inflammatory muscle disease and can present as sudden-onset heart failure. Prompt institution of immunosuppressive treatment is indicated in these cases. An endomyocardial biopsy may be helpful in differentiating overt myocarditis from the myocardial fibrosis commonly present in scleroderma patients.

RENAL INVOLVEMENT

KEY POINTS

Scleroderma renal crisis (SRC) is a life-threatening condition that occurs in 5% to 10% of scleroderma patients.

Risk factors for SRC include early diffuse skin disease, use of corticosteroids, and the presence of anti-RNA polymerase III antibodies.

Early pharmacologic intervention with angiotensin-converting enzyme inhibitors is crucial to control and possibly reverse the disease process.

Renal involvement in scleroderma is classically characterized by the abrupt onset of very high blood pressure (malignant hypertension), elevated plasma renin, and rising serum creatinine reflective of acute renal failure, along with a constellation of symptoms and clinical manifestations such as headaches, malaise, hypertensive retinopathy, encephalopathy, and pulmonary edema, usually referred to as *scleroderma renal crisis* (SRC). Renal disease in scleroderma can also be asymptomatic, and despite the high prevalence of histopathologic renovascular lesions typical of scleroderma vasculopathy, clinically important renal dysfunction, independent of scleroderma renal crisis, is seen in only a minority of patients.¹⁰⁵ Although SRC is the most recognized renal complication, abnormal renal function can be explained by factors other than intrinsic scleroderma renal disease such as medication side effects, comorbid conditions, or associated heart, gastrointestinal, or lung disease. One survey suggested that mild unexplained proteinuria without loss of renal function or evidence of glomerular disease is a common sign of renal disease in scleroderma.¹⁰⁶ A superimposed inflammatory kidney disease can also occur in scleroderma. Several cases of pauci-immune necrotizing crescentic glomerulonephritis associated with myeloperoxidase (MPO)-specific antineutrophilic cytoplasmic antibodies (ANCA) have been reported in scleroderma patients with a presentation mimicking SRC.¹⁰⁷

SRC needs to be considered in scleroderma patients with sudden and severe elevation of blood pressure, with or without renal failure; in patients with sudden renal failure, with or without hypertension; and in patients with sudden-onset microangiopathic hemolytic anemia, with or without hypertension or renal failure. Nonmalignant hypertension alone without signs of renal dysfunction or mild urine abnormalities is unlikely to be due to SRC. Scleroderma renal crisis occurs in 5% to 10% of patients and mostly in those with diffuse scleroderma. It usually is encountered within the first 2 to 4 years from disease onset. The estimated median duration of scleroderma at the time of SRC diagnosis is 8 months.^{108,109} Occurrence in later disease is uncommon.¹⁰⁸ Patients at greatest risk of developing SRC are those with diffuse cutaneous scleroderma, particularly those with the rapidly progressive skin disease. SRC is a rare complication in patients with limited scleroderma (approximately 1% to 2%). African-Americans and patients with diffuse skin disease who are treated with a high dose of corticosteroid (>40 mg/day of prednisone) or low-dose cyclosporine are at increased risk of developing an SRC. A

long-term low dose of prednisone may also be a risk factor for SRC. For this reason, it is recommended to avoid corticosteroids or to use doses less than 10 mg daily if necessary. Renal crisis is also associated with a positive ANA (speckled pattern) anti-U3-RNP and usually is not seen in patients with anticentromere antibodies. Antibodies to RNA polymerase III have been found in about 60% of patients with SRC in one survey.¹⁰⁸ Although antitopoisomerase I antibodies are prevalent in patients with diffuse skin disease, no association between their presence and SRC has been reported. Nonmalignant hypertension, abnormal urinalysis, and isolated increases in plasma renin activity are not predictors of an SRC.¹¹⁰

Patients experiencing SRC present with typical signs of malignant hypertension, including headache, altered vision, signs of congestive heart failure, florid pulmonary edema, confusion, or neurologic signs secondary to hypertensive encephalopathy in the setting of an abnormally high blood pressure, usually above 150/90 mm Hg. Hypertensive encephalopathy is characterized by acute or subacute onset of lethargy, fatigue, confusion, headaches, visual disturbances (including blindness from hypertensive retinopathy), seizures, or cerebral hemorrhage. In about 10% of cases, SRC occurs with normal blood pressure. New-onset anemia, asymptomatic pericardial effusion, and cardiac disease may precede an SRC. Laboratory testing at onset may show normal or high creatinine, modest to absent proteinuria, and/or microscopic hematuria. Renal insufficiency usually is not the presenting problem in an SRC but rather is a late complication of untreated disease. However, a rapid rise in serum creatinine can occur over several days with a fairly benign urinalysis—less than 2 g of protein excretion in 24 hours—and a mild hematuria with some granular casts. A microangiopathic hemolytic anemia and thrombocytopenia can accompany or precede an SRC and may be the only finding in a normotensive patient. This presentation with normotensive SRC usually entails a worse prognosis. Distinguishing SRC-associated thrombotic microangiopathy from idiopathic thrombotic thrombocytopenic purpura may be difficult but is important because treatments differ. Accurate assays for ADAMTS (a disintegrin and metalloproteinase [ADAM family] with thrombospondin-1 domains)-13 activity can be helpful because its level should be normal in scleroderma.

Poorer outcome is more frequent among males and among patients presenting with creatinine greater than 3 mg/dL (265 mmol/L). Approximately two-thirds of patients with SRC will require renal support with dialysis, but about half will recover function and be able to discontinue therapy, usually within several weeks, most before 6 months.¹⁰⁸ However, cases of recovery from up to 24 months of dialysis support have been reported, distinguishing SRC from other causes of renal failure. The renal crisis truly mimics malignant hypertension, with rapidly progressive renal failure secondary to microvascular disease, vasospasm, and tissue ischemia. The characteristic lesion of vascular disease such as intimal hyperplasia or luminal narrowing involving in particular the renal arcuate arteries is detected even in patients without SRC. Although the renal pathology is now well described, the pathogenesis of the renal crisis remains poorly understood. It is assumed that intrinsic renal vessel disease is complicated by an intense vasospasm

triggering high levels of plasma renin, which results in malignant hypertension.

Before the discovery of angiotensin-converting enzyme (ACE) inhibitors, hypertensive renal crisis had almost uniformly a fatal outcome. In contrast, patients treated with ACE inhibitors have a good outcome 60% of the time, and death or end-stage renal disease is now much less common. The mortality rate at 1 year associated with SRC has decreased from 76% to less than 15%. However, despite aggressive antihypertensive therapy, the 5-year survival of patients with SRC remains only 65%. Although ACE inhibitors are standard therapy in SRC, it remains unclear whether other related drugs such as angiotensin receptor blockers (ARBs) can be effective in treating or preventing a crisis. Endothelin and other mediators of vascular disease are implicated in the pathogenesis of SRC; thus interference with endothelin function by a specific inhibitor may offer a novel therapeutic approach. A vasodilating prostaglandin (prostacyclin) may also provide rapid control of blood pressure while improving renal blood flow. The overall outcome in SRC remains unsatisfactory in terms of acute disease outcome, morbidity, and need for renal transplantation or long-term renal support with dialysis. Data suggest that use of an ACE inhibitor before a crisis does not prevent an SRC.¹⁰⁸

Any newly developed hypertension in a scleroderma patient should be urgently evaluated because the key to successful therapy is early detection and rapid intervention (Figure 84-15). Patients with SRC should be hospitalized and immediately started on an ACE inhibitor. Captopril, a rapid-acting ACE inhibitor, should be started, to allow dose increases until systolic blood pressure is down by 20 mm Hg/24 hr while avoiding hypotension. Treatment continues

with an ACE inhibitor even if creatinine continues to rise. When full doses of an ACE inhibitor are not controlling blood pressure, other antihypertensive medications may be added, including calcium channel blockers, endothelin inhibitors, and prostacyclin or an ARB (which is infused). Some patients continue to have progressive renal failure despite attaining control of blood pressure. Other causes of renal disease always need to be considered, especially in patients with limited scleroderma, and in those with a high level of proteinuria or abnormal urinalysis such as red cell casts. Renal biopsy should be done to confirm the diagnosis and to gain insight into the prognosis by determining the degree of renal damage. Detection on kidney biopsy of other forms of glomerular inflammation is important in that it will dictate a different specific treatment approach.

Successful renal transplantation has been performed in scleroderma patients, providing an overall survival benefit over long-term dialysis. Renal allograft survival at 3 years is about 60%, which is comparable with the rate observed in systemic lupus erythematosus. It is not recommended to pursue renal transplantation until it is clear that recovery will not spontaneously occur. This can be determined in part by assessing the degree of damage on renal biopsy and by waiting at least 6 months (some suggest 2 years) after recovery from the acute crisis. Recurrence of SRC is uncommon (5%) after renal transplant.

MUSCULOSKELETAL INVOLVEMENT

Musculoskeletal symptoms are almost always present in scleroderma, usually are multifactorial in origin, and often are the initial symptoms of the disease. The most common

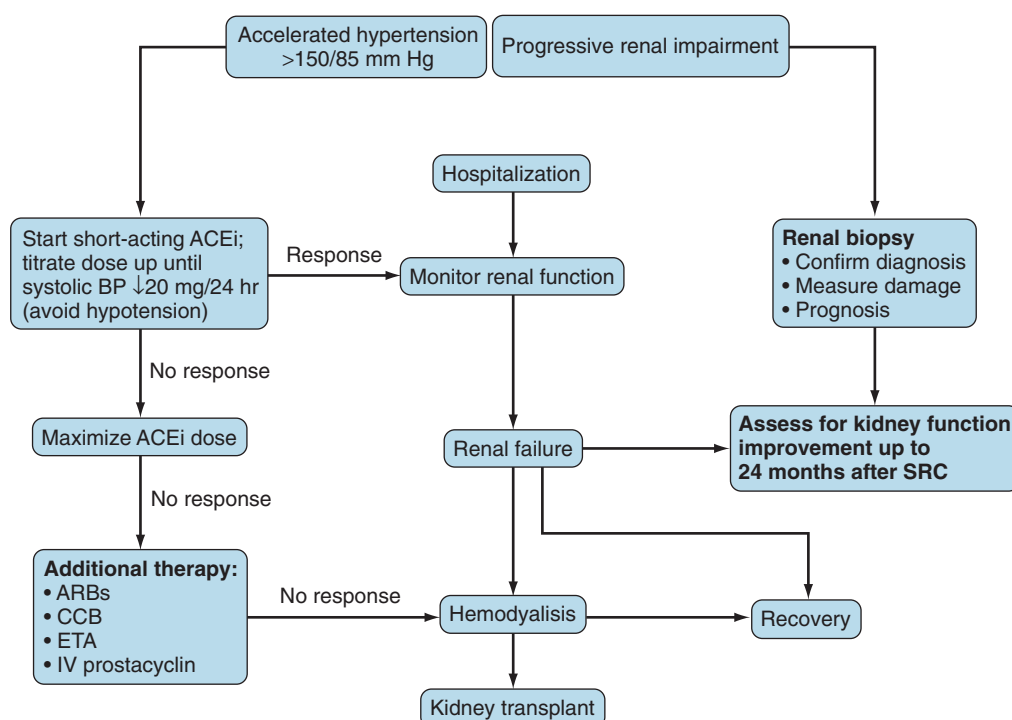

Figure 84-15 Management of scleroderma renal crisis. ACEi, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; ETA, endothelin receptor antagonist; IV, intravenous; SRC, scleroderma renal crisis.

symptoms are nonspecific pain, stiffness, and diffuse muscular discomfort that mimics a flu-like syndrome. Impaired hand function, characterized by decreased hand mobility, reduced dexterity, and decreased grip force, is in particular a major source of difficulty in performing activities of daily living. The degree and type of musculoskeletal disease vary a great deal and are influenced by the duration of disease, the level of overall disease activity, and the subtype of skin involvement. For example, in early diffuse scleroderma, pain is often widespread in areas of skin inflammation and advancing fibrosis that can involve joint structures, tendons, subcutaneous tissue, and underlying muscle. In later-stage diffuse disease, joint contractures and muscle atrophy are often associated with pain and loss of function, causing significant disability. In limited scleroderma patients, puffy fingers and loss of hand function and grip may be the only musculoskeletal symptoms throughout the disease course. Although histologic evidence suggests that synovitis occurs, arthralgias, pain, and stiffness without signs of frank arthritis constitute the usual clinical picture. However, overlap syndromes of rheumatoid-like polyarthritis or inflammatory muscle disease can dominate the clinical picture in an individual patient.

In the early edematous phase of diffuse scleroderma, patients often are diagnosed with a carpal tunnel syndrome due to soft tissue swelling and inflammation in the hand and wrist area. Erosive arthritis with joint space narrowing can be seen, but soft tissue swelling, periarticular osteopenia, and contractures of the joint are more common. Distal bone resorption, osteolysis, and periarticular calcinosis are found in the fingers of patients with later-stage diffuse scleroderma. Contractures of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints are most common, and rarely of the distal interphalangeal (DIP) joint. Patients with diffuse skin disease develop contractures of large joints, including wrist, elbows, shoulders, hips, knees, and ankles. These contractures are the hallmark of severe scleroderma and are associated with fibrosis and ankylosis of the joint, resulting from disease in the overlying skin, fascia, joint capsule, and tendons.

Tendon friction rubs can be felt as a coarse crepitus over joints or over the forearm or lower leg with adjacent joint movement. These rubs are thought to be secondary to low-grade tenosynovitis, local edema, and fibrosis of the tendon sheath, fascia, and joint structures. Friction rubs are seen primarily in patients with diffuse skin disease; when present, they are an indicator of a poor overall prognosis. They are found in about 15% to 30% of patients and are more common in those with diffuse skin disease and in patients with antitopoisomerase, anti-RNA polymerase, or anti-U3-RNP antibodies.¹¹¹

The prevalence of signs of joint inflammation in scleroderma is estimated in relatively small observational studies to be about two-thirds of patients.^{112,113} A large multicenter survey reported the frequencies of synovitis, tendon friction rubs, and joint contractures to be 16%, 11%, and 31%, respectively.¹¹⁴ Synovitis, tendon friction rubs, and joint contractures are more likely to occur together and are more prevalent in patients with the diffuse cutaneous subset. These manifestations also tend to be associated with severe vascular, muscular, renal, and interstitial lung involvement. Synovitis, joint contracture, and tendon friction rubs are

associated with more severe disease and with systemic inflammation.

Erosive arthritis is commonly associated with periarticular calcinosis (Figure 84-16A) and can be seen with significant bone loss or osteolysis. A radiologic survey of 120 patients found abnormalities including erosion (21%), joint space narrowing (28%), arthritis (defined by concomitant erosion and joint space narrowing) (18%), radiologic demineralization (23%), acro-osteolysis (22%), flexion contracture (27%), and calcinosis (23%).¹¹⁴ Radiologic studies using ultrasonography and MRI confirm that hand involvement is striking, with articular, bone, and soft tissue changes.^{115,116} Resorption of distal phalanges was significantly associated with digital ulcers and extra-articular calcification; flexion contracture was associated with the diffuse cutaneous form and with high Health Assessment Questionnaire (HAQ) disability scores.¹¹⁷ Calcinosis is most often seen in patients with digital ulcers but was similarly observed in patients with the diffuse or limited cutaneous subtype. Calcinosis is often seen in the subcutaneous tissue in areas of trauma such as the extensor surfaces of the forearms, elbows, or patellae. Unlike the more diffuse calcinosis seen in myositis patients, calcium deposits in scleroderma tend to be found in clusters around joints and sites of trauma. These deposits can restrict joint motion and may be associated with acute inflammation similar to a gouty arthritis, or the deposits can rupture through the skin, weeping a thick white material. Once the skin is broken, secondary infection can occur.

Erosive polyarthritis, seemingly specific for scleroderma, or seropositive rheumatoid arthritis can occur in patients with limited or diffuse skin disease. However, the prevalence of scleroderma with rheumatoid arthritis overlap is unusual (1% to 2%) with an estimated incidence of 5%.^{114,118,119} This is confirmed by the low frequency of anticyclic citrullinated protein antibodies found in patients with scleroderma and arthritis. When an inflammatory arthritis is present, traditional medications used in rheumatoid arthritis can be helpful. One case series demonstrated that the tumor necrosis factor (TNF) inhibitor etanercept appeared to be efficacious in improving active inflammatory joint disease in a subset of scleroderma patients, and it was generally safe and well tolerated.

A sense of weakness in the muscles of the hands, arms, and legs is very common (80%) and can be subtle or profound. One study found measurable weakness in 30% of patients with proximal more than distal strength compromised. Myopathy in an individual scleroderma is often multifactorial, but patients with myopathy are at increased risk for poor outcome and decreased survival.¹²⁰ Weakness is often caused by muscle atrophy secondary to the inflexibility due to joint disease and fibrotic skin with lack of usual mobility and exercise. It can also occur because of malnutrition resulting from scleroderma bowel disease. Muscle weakness in scleroderma may be secondary to direct muscle disease. In diffuse scleroderma, fibrosis can extend into the striated muscle, causing muscle atrophy and clinical weakness. This has been called a *fibrosing myopathy*. It presents in the setting of severe diffuse skin disease with joint contractures and mild elevation of creatine phosphokinase (CPK). Electromyography (EMG) demonstrates nonirritable myopathy, and muscle biopsy shows little inflammation,

Figure 84-16 A, Hands of a scleroderma patient showing reabsorption of distal phalanges corresponding to radiographic evidence of (B and C) acroosteolysis, calcinosis, and joint erosions.

fibrosis, and type 2 muscle atrophy. The fibrosing myopathy does not respond to traditional anti-inflammatory medications, including corticosteroids. This type of muscle disease is associated with cardiomyopathy, heart failure, and arrhythmia that can be severe and irreversible.¹²⁰

Approximately 5% to 10% of scleroderma patients have an inflammatory muscle disease that can follow the same course as polymyositis and other forms of idiopathic inflammatory myopathy. Patients present with rapid proximal muscle weakness associated with high CPK. EMG shows irritable myopathy, and muscle biopsy is typical of an inflammatory myositis. In some cases with severe polymyositis, myocarditis can occur with heart failure. High levels of anti-PM/Scl-100 antibodies are found in about 4% of patients with SSc, and these patients often present with acute inflammatory muscle disease. Patients with muscle weakness should be fully evaluated for underlying causes with the use of laboratory measures of muscle enzymes, electromyographic studies, magnetic resonance imaging, and muscle biopsy. These studies will help differentiate inflammatory muscle disease from other forms of myopathy.

ENDOCRINE INVOLVEMENT

Endocrine dysfunction can complicate the course and management of scleroderma patients. The most common endocrine problem associated with scleroderma is thyroid disease, and the frequency of other endocrinopathies is similar to that of the general population. Thyroid disease is reported in 10% to 15% of patients with scleroderma.^{121,122} A case-control study found a 10 to 14 times increased risk of hypothyroidism in scleroderma.¹²³ Evidence for both fibrosis of

the thyroid and autoimmune injury exists. Patients with features of the CREST syndrome (subcutaneous calcinosis, Raynaud's phenomenon, esophageal hypomotility, sclerodactyly, and telangiectasias) are more likely to have hypothyroidism than those with diffuse skin disease. An autoimmune basis for thyroid disease is suggested by one series, which found Hashimoto's thyroiditis in 6% and Graves' disease in 3% of patients.¹²⁴ A survey of 719 scleroderma patients found that 273 (38%) had at least one other autoimmune condition; the most frequent was autoimmune thyroid disease.¹²⁵ Thyroid autoantibodies are commonly found in scleroderma patients with hypothyroidism. In addition, the association of CREST syndrome with autoimmune hypothyroidism and primary biliary cirrhosis has been reported, suggesting multiple autoimmune targets in these patients. Thyroid disease may not be recognized in patients with subclinical disease or with symptoms associated with chronic multisystem disease. It is recommended that thyroid function should be monitored periodically, especially in patients with limited scleroderma with the CREST syndrome and in those with long-standing disease.

OTHER ASSOCIATED MANIFESTATIONS

It must be recognized that in patients who have scleroderma, several less common and often forgotten complications of this disease may require attention. Awareness of these associated problems can improve quality of life and prevent undue distress. Bone disease can occur for a variety of reasons. Most patients with scleroderma are women who are near or in menopause, and therefore are at risk for osteoporosis and its complications. This risk is increased by

the chronic inflammatory nature of the disease, disuse, and several commonly used medications. Malabsorption and lack of sun exposure may lead to vitamin D deficiency, and bowel dysfunction can limit calcium intake. Avascular necrosis of carpal bones of the wrist is reported and is thought to be secondary to scleroderma peripheral vascular disease. In addition, osteolysis or bony resorption of the tips or tufts of the fingers, middle phalanges, distal radius, and ulna bones (less commonly, the distal clavicle, ribs, mandible, and distal toes) may occur (Figure 84-16B and C). Acro-osteolysis is fairly common, presenting with shortening of the finger or pain of the fingertip. Osteolysis is thought to be a manifestation of peripheral vascular disease and poor nutritional blood flow on affected bones. Neurologic complications can be a significant unrecognized problem. The central nervous system is generally spared in scleroderma, but unilateral or bilateral trigeminal neuralgia is known to occur in a subset of patients. Peripheral neuropathy occurs in a higher percentage of patients than expected owing to multiple causes, including nutritional deficiency from gastrointestinal disease, entrapment neuropathy, vasculitis, or vasculopathy of small vessels typical of scleroderma vascular disease. Carpal tunnel syndrome can complicate diffuse scleroderma and may occur in patients with associated inflammatory joint disease.

Muscle weakness is very common, and the presence of a myopathy is associated with a poor prognosis. Multiple factors, including inflammatory polymyositis, disuse atrophy, malnutrition, medications, and a fibrosing myopathy associated with diffuse scleroderma skin disease, can cause muscle dysfunction. Autoimmune hepatitis and biliary cirrhosis are reported in patients with the CREST syndrome. It is recommended that all patients with scleroderma be screened for associated autoimmune-mediated liver disease because it usually responds to immunosuppressive therapy.

Dry eyes (keratoconjunctivitis sicca) and/or mucous membranes (xerostomia) occur in about 25% of patients. Dry eyes may occur as the result of severe facial periorbital skin fibrosis inhibiting full closure of the eyelids. Topical artificial tears should be used frequently in these cases. Facial changes alter oral aperture and decrease facial flexibility. Vertical lines around the lips and thinning of the lips along with pinching of the nose affect self-esteem, especially in younger women. A decreased oral aperture prevents easy daily oral hygiene and dental procedures. Loosening of the teeth happens because of loss of normal periodontal ligament attaching the tooth to the alveolar bone. Decreased saliva and difficulty performing usual dental hygiene can lead to significant periodontal disease. Treatment of oral manifestations requires early referral for experienced dental care and frequent cleaning with fluoride treatment. Pilocarpine and cevimeline are agonists for the muscarinic cholinergic receptors that can increase saliva and improve symptoms of xerostomia.

Most data suggest normal fertility in scleroderma, but during pregnancy, risk for hypertension, scleroderma renal crisis, or premature fetal loss is increased. Sexual performance is often affected, particularly in women with diffuse disease. Decreased sexual satisfaction is associated with painful inflexible joints, dry vaginal membranes, and general fatigue. Erectile dysfunction and associated impotence among male scleroderma patients have been reported in

more than 80% of men with scleroderma. This results from local fibrosis of the corporeal smooth muscle and scleroderma microvascular disease. Psychogenic and medication-induced sexual dysfunction must be considered.

Several causes of lower extremity lesions can occur, including skin fibrosis, stasis dermatitis, lipodermatosclerosis, panniculitis, subcutaneous calcinosis, and leg ulcers. Leg ulcers may result from traumatic breakdown of atrophic fibrotic skin, ischemic ulcers secondary to scleroderma vascular disease, vasculitis, and occlusive vascular events resulting from an associated hypercoagulable state. Livedoid vasculopathy is a rare complication causing skin ulcerations on the lower leg and foot as the result of small vessel vasculitis or small vessel thrombosis.

PSYCHOSOCIAL ASPECTS

Scleroderma is a disease that can alter virtually every aspect of the patient's life. Although scleroderma is often mild in its expression, the patient is now faced with a life crisis and must deal with a rare chronic disease that is complex and is not completely understood by the medical community. Patients learn that scleroderma is potentially a life-threatening disease that alters physical capacity and can be disfiguring. At the onset of the disease, patients are often confused, anxious, and frightened. Fear and misunderstanding become a major source of distress. Studies of psychosocial adjustment support the conclusion that a substantial proportion of patients with scleroderma have difficulty adapting to the disease and have reduced quality of life measures. Although little evidence suggests that scleroderma directly affects the central nervous system with a direct organic cause for altered mental status, a complex array of medications used to treat the disease and its complications may have some influence on mood and sense of well-being.

Psychosocial aspects of the disease do not appear to be consistently influenced by age, gender, ethnicity, education, or marital status. However, some data suggest that being disabled with low financial income leads to higher psychological distress. Evidence suggests that depression in scleroderma patients is common and is related more to the patient's personality, the degree of pain, and the level of social support than to actual disease severity. Disease-related disability, as measured by the Health Assessment Questionnaire Disability Index (HAQ-DI), is a more important predictor of adjustment problems than are disease symptoms related to severity. Pain and fatigue are common in scleroderma. Together with depressive symptoms, they are the most significant determinants of physical functioning and social adjustment—two important components of health-related quality of life—in patients with limited and diffuse disease subtypes.

Personality traits influence the degree of psychological adjustment. Patients with scleroderma who describe themselves as anxious, worried, tense, or detail-oriented are more likely to be depressed than patients who describe themselves as agreeable or extraverted and outgoing. Disease unpredictability and lack of control cause increased distress. High self-reported uncertainty is related to poor adjustment. Thus, increasing the patient's understanding of the disease and expectations through education may reduce

uncertainty and improve quality of life. Body image dissatisfaction is a significant concern. Patients are distressed by disease-related changes in visible parts of their body, especially the fingers and hands. A survey found that tight skin and facial changes were not as distressful as hand deformity with finger contractions and hand dysfunction. Sexual function is affected in both men and women with scleroderma. A significant proportion of men experience erectile dysfunction. Women with scleroderma, particularly those with diffuse skin disease, have high levels of sexual impairment compared with women with other chronic diseases for which sexual function has received greater attention. Both may have a decreased sexual drive during the disease course. The impact of sexual function on quality of life is not well studied, but it exists as a problem and should be appropriately addressed as part of comprehensive care.

Psychological factors with demonstrated relevance to scleroderma include pain, depression, and distress about disfigurement, physical function, and social function. Although these dimensions of quality of life are interrelated, pain, depression, and distress about disfigurement are common and may respond to psychological intervention. This begins with providing compassionate support beyond just ordering medications. It is important to spend time in a comfortable setting educating patients about scleroderma, providing a clear understanding of the degree of their disease and explaining to them what they need to do and what can be done for relief. Having insight into social support and life circumstances, including financial distress, work environment, and family structure, provides a framework for helping to decrease external distress. For example, a family conference held to explain the reality of the health situation or the needs of the patient can reduce home tension and can clarify the patient's capacity in their family role. An adjustment in the work environment (e.g., permission for a space heater) can make a difference. Clearly, effective social support improves quality of life. Follow-up visits that provide time to discuss issues of coping and social support are most important. Recognizing the personality of patients while addressing their specific concerns is helpful. Treating underlying depression and especially providing effective management of disease-related pain help to improve quality of life and reduce social and psychological distress. Body image dissatisfaction is a significant concern in women with scleroderma and should be assessed routinely. Early identification and treatment of body image dissatisfaction may help to prevent depression and psychosocial impairment in this population. The possibility of premature death from the disease is a major cause of fear and needs to be addressed with the patient and the family. Most often, life expectancy is not influenced by the disease, yet patients fear death because they have scleroderma. When a patient is facing death from severe disease, appropriate honest and sensitive support must be provided.

THERAPEUTIC APPROACH FOR DISEASE MODIFICATION

Immunotherapy

Scleroderma is thought to be an inflammatory connective tissue disorder triggered by an autoimmune process.⁶⁶

Nonselective immunosuppressive treatments are usually employed in scleroderma to treat specific organ manifestations such as early progressing skin disease, active interstitial lung disease, and underlying inflammatory joint or muscle disease (Table 84-5). Cyclophosphamide (CYC) has shown some modest efficacy in scleroderma-related ILD in a randomized placebo-controlled trial. Current therapeutic protocols use CYC as a daily oral regimen or as monthly intravenous (IV) therapy, until control of disease is achieved. The CYC is often followed by maintenance treatment with azathioprine (AZA) or mycophenolate mofetil (MMF), agents that have antiproliferative effects on inflammatory cells and in particular on activated T and B lymphocytes.¹²⁶ Uncontrolled studies suggest benefit of MMF in both ILD

and active scleroderma skin disease.¹²⁷⁻¹²⁹ Evidence supporting the use of AZA as a primary agent to treat scleroderma-related ILD is weak and remains limited to small retrospective studies. Two open-label trials support its role as maintenance therapy after primary CYC immunosuppression.¹³⁰⁻¹³²

Methotrexate (MTX) is frequently used in scleroderma to treat associated inflammatory arthritis and myositis. MTX efficacy in skin disease and lung function has been investigated in two randomized placebo-controlled trials showing only a small benefit on skin scores after 6 months (weekly intramuscular injections) or 12 months (weekly oral therapy), respectively.^{133,134} Based on the findings of these studies, many experts use MTX for active skin disease.

Selective immunotherapy has also been used in scleroderma (see Table 84-5). T lymphocyte-directed treatments such as cyclosporin A, sirolimus (rapamycin), and antithymocyte globulin (ATG) have shown some benefit.^{135,136} However, these studies generally were small and were limited by drug toxicity. The use of extracorporeal photopheresis (ECP) has been reported with modest improvement in skin disease but lack of any efficacy on internal organ manifestations.¹³⁷ This approach is not currently supported. Preliminary studies of rituximab, a chimeric immunoglobulin (Ig)G1 monoclonal antibody directed against CD20, a surface molecule expressed on early pre-B and mature B cells, have not yet demonstrated solid evidence of clinical benefit.^{138,139} However, therapeutic strategies based on B cell depletion remain an active area of research. Administration of intravenous immunoglobulins (IVIg) to scleroderma patients has been reported in uncontrolled studies with some evidence that it can improve skin fibrosis or joint disease.

Studies of cell-based immunotherapy using autologous hematopoietic stem cell transplantation (HSCT) preceded by myeloablative conditioning regimens are under way for severe cases of scleroderma. Overall, preliminary data suggest that this approach is effective in improving skin fibrosis and providing stabilization of the lung and other organ function.^{140,141} However, significant concern regarding toxicity and treatment-related mortality exists such that this approach is still considered investigational and is used only in patients with life-threatening diffuse scleroderma. Nonmyeloablative (immunoablative) conditioning regimens with or without HSCT have demonstrated similar results.^{142,143}

Treatment of Fibrosis

To date, no drugs have proved able to reverse the fibrotic disease process in scleroderma, but several potential agents are being used off-label or are under investigation. Their use is still based on *in vitro* data, animal studies, or case series because formal well-designed controlled trials are still missing.

D-Penicillamine is a chelating agent that blocks collagen cross-linking and thus has the potential to have an antifibrotic effect. Several case reports and retrospective reviews have suggested that D-penicillamine is beneficial.¹⁴⁴ A double-blind, randomized clinical trial comparing the efficacy of low-dose versus high-dose D-penicillamine in early diffuse scleroderma found no significant difference between skin scores of the two groups at 24 months.¹⁴⁵ Given the

potential toxicity of D-penicillamine, its lack of effectiveness in the only controlled trial, and the long duration before benefit was achieved in several uncontrolled surveys, the drug has fallen out of favor and generally is not used.

Transforming growth factor-beta (TGF- β) is a cytokine known to promote fibroblast proliferation and differentiation, in addition to upregulation of collagen and extracellular matrix synthesis. Therefore, it represents an appealing target to specifically control progression of collagen and extracellular deposition in tissues. A human recombinant neutralizing TGF- β antibody was studied versus placebo in a relatively small phase I/II trial in patients with early diffuse scleroderma.¹⁴⁶ No clinical benefit was observed when skin score or lung function testing parameters were evaluated. Although the results of this study were negative, it does not negate the idea that another more potent neutralizing antibody might be helpful.

Imatinib, dasatinib, and nilotinib are small molecules that inhibit the tyrosine kinase activity of the abl-kinases and platelet-derived growth factor (PDGF) receptors, thus interfering with important profibrotic pathways activated in scleroderma. In addition, dasatinib inhibits Src kinases, which are also involved in fibroblast differentiation and secretory function.¹⁴⁷ Several uncontrolled trials with tyrosine kinase inhibitors are currently under way, with early data analysis reporting conflicting results. Adverse events were common, including fluid retention, nausea, fatigue, and elevation of creatine kinase. Therefore, although a potent antifibrotic effect has been shown by tyrosine kinase inhibitors *in vitro* or in animal models, clinical studies to date have not provided solid evidence for their use in treating skin and systemic fibrosis in scleroderma. Formal clinical trials are needed.

Halofuginone, a plant-derived alkaloid with antifibrotic properties via inhibition of TGF- β and T cell activation, is known to reduce collagen production in animal models. Only limited use of topical halofuginone therapy in scleroderma skin disease is reported with some encouraging results.¹⁴⁸ Rosiglitazone is an agonist of peroxisome proliferative-activator receptor gamma (PPAR- γ) and has been shown to suppress *in vitro* fibroblast production of collagen and to alleviate fibrosis in the bleomycin-induced scleroderma mouse model.¹⁴⁹ Pirfenidone (5-methyl-1-phenylpyridin-2[1H]-one) is a novel antifibrotic agent with evidence of benefit in patients with idiopathic pulmonary fibrosis (IPF).¹⁵⁰ Clinical trials in scleroderma have not been performed. Neutralizing antibodies against connective tissue growth factor (CTGF) can effectively suppress the development of skin fibrosis in animal models, and anti-CTGF therapy is now under consideration to treat scleroderma.¹⁵¹

Treatment of Vascular Disease

Although scleroderma is generally considered a fibrosing disorder, it is well recognized that underlying vasculopathy plays a fundamental role in its pathogenesis and associated tissue injury. In RP, small and medium-sized peripheral blood vessels involved in tissue nutrition and body thermoregulation are affected. The pathologic and clinical consequences of scleroderma vascular disease are not limited to

the skin but are widespread and are found in all involved organs. Currently, no guidelines have been put forth for the treatment of scleroderma vascular disease. Therefore, pharmacologic therapies are focused on the treatment of organ-specific disease such as scleroderma renal crisis, PAH, and RP. Conventional treatment strategies have been limited to the use of nonspecific vasodilator agents (see Raynaud's phenomenon section). More recently, it has been appreciated that agents targeting specific biologic processes involved in vascular disease (i.e., prostacyclin, endothelin antagonists, and phosphodiesterase inhibitors) may have a broader beneficial effect on scleroderma (see Raynaud's phenomenon and pulmonary hypertension section).

SUMMARY OF CURRENT PRACTICAL RECOMMENDATIONS FOR TREATMENT

The key to current management of scleroderma is to not isolate treatment to one problem that seems to be dominant, but to appreciate the complexity and dynamics of this multisystem disease (Table 84-6). It is clear that use of just one drug is not effective in managing scleroderma, and that long-term therapy is required with possible adjustments based on specific clinical circumstances. A combination therapy approach that attempts to treat the immune response, the vascular disease, and the underlying tissue fibrosis is recommended.

Patients with severe RP should be on vasodilators and antiplatelet therapy with aspirin. Vasodilator treatment should start with a calcium channel blocker, with a second agent added if needed. This can be a phosphodiesterase inhibitor or intermittent intravenous prostacyclin (it is hoped that oral prostacyclin will be available soon). If digital ulcers are recurring, then the addition of an endothelin inhibitor or a statin is suggested.

Patients with hypertensive renal disease should be treated urgently with an ACE inhibitor or, if needed, with additional ARBs or antihypertensives, including calcium

channel blockers or a prostacyclin analogue. The use of ACE inhibitors to prevent a scleroderma renal crisis is not recommended.

All patients need periodic professional dental care, and if loss of saliva is noted, the use of pilocarpine or cevimeline is recommended. Patients with upper gastrointestinal disease should be treated with lifestyle changes such as improving their eating habits with proton pump inhibitors, in case of unremitting symptoms with a prokinetic drug (metoclopramide, domperidone). If the lower intestinal tract is involved, then rotating antibiotics can improve episodes of pseudo-obstruction, diarrhea, or malabsorption.

First-line therapy for active skin disease has not yet been established, but we recommend immunosuppressive therapy based on severity and level of disease activity. Although most recommend methotrexate, we prefer mycophenolate for mild disease and cyclophosphamide for severe aggressive disease (daily oral, monthly IV). More innovative therapies are needed and may include antithymocyte globulin, immunoblation or myeloablation with or without hematopoietic stem cell rescue, and intravenous gamma globulin given alone or in combination with other immunosuppressive agents. Participation of patients in new clinical trials should be pursued.

Active interstitial lung disease should be treated with immunosuppressive therapy. Induction therapy with cyclophosphamide (6 to 12 months; daily oral or monthly IV therapy) followed by maintenance (several years) with mycophenolate or azathioprine is recommended. Mycophenolate or azathioprine alone is a reasonable alternative.

Pulmonary vascular disease and PAH are best treated with vasoactive drugs, including endothelin-1 inhibitors, phosphodiesterase inhibitors, or prostacyclin analogues, given alone or in combination. The role of anticoagulation or immunosuppressive agents is not yet defined. Treatment of associated heart failure is most important.

Cardiac disease should be treated with vasoactive drugs such as calcium channel blockers, other antihypertensive agents, diuretics, and antiarrhythmic medications.

Table 84-6 Current Recommendations for Treatment of Scleroderma

Manifestation	Primary Therapy	Alternative/Second-Line Therapy
Raynaud's phenomenon	Vasodilators (CCB) Antiplatelet	PDE5 inhibitors, prostacyclin, endothelin antagonists
Hypertensive renal disease	ACE inhibitors	ARBs, CCB, prostacyclin, renal transplant (wait at least 24 mo)
GI involvement	Upper GI Dental/periodontal care, lifestyle modifications, proton pump inhibitors, prokinetics Lower GI Probiotics, rotational antibiotics	EGD to treat stenosis and/or GAVE Total parenteral nutrition
Skin	Mycophenolate mofetil, cyclophosphamide	IVIG, ATG, research trial (severe cases)
Interstitial lung disease	Cyclophosphamide, mycophenolate mofetil, azathioprine	Research trial
Pulmonary arterial hypertension	PDE5 inhibitors, endothelin antagonists, prostacyclin	Combination therapy, atrioseptostomy, lung transplant, research trial
Cardiac involvement	Heart failure therapy, diuretics, CCB	Immunosuppression (myocardial inflammation)
Joints	Prednisone, methotrexate, TNF inhibitors	IVIG (if contractures and rubs are present), PT/OT
Muscles	Prednisone, methotrexate, azathioprine	IVIG
Psychosocial	Antidepressants, pain control, sleep control	Support group

ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; ATG, antithymocyte globulin; CCB, calcium channel blockers; EGD, esophagogastroduodenoscopy; GAVE, gastric antral vascular ectasia; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; IVIG, intravenous immunoglobulin; PDE5, phosphodiesterase-5 inhibitor; PT/OT, physical therapy/occupational therapy; TNF, tumor necrosis factor.

Immunosuppression should be used if inflammatory muscle or pericardial disease is present.

Inflammatory arthritis should be treated in a similar fashion to the approach used in treating rheumatoid arthritis. However, a fibrosing process causing a nonerosive arthropathy with friction rubs and joint contractures is best treated with the same medications used for active scleroderma skin disease.

Treatment for muscle disease will vary depending on the presence of inflammatory myositis or a nonirritable fibrosing myopathy. The former is treated with corticosteroids, methotrexate, or other immunosuppressive agents effective in immune-mediated polymyositis. The fibrosing process is best treated with the same approach used for scleroderma skin disease.

All patients need emotional and physical support. Scleroderma is a painful disease, and managing pain is essential for reducing depression and improving quality of life. This may require the use of sleep aids (e.g., lorazepam, zolpidem) and/or intermittent use of narcotics. Physical and occupational therapy is most important early in the course of the disease to reduce pain and improve activities of daily living. Family counseling helps the patient cope by providing a clear understanding of what is needed at home. Adjustment of the work environment (e.g., limiting time at work, adjusting room temperature, changing work

assignment) or helping to obtain disability support is also important. Open communication between the physician and the patient provides an essential element of care.

LOCALIZED SCLERODERMA

Localized scleroderma is a nonsystemic skin disease that is seen primarily in children.¹⁵² It can be divided into five major types: plaque morphea, generalized morphea, bullous morphea, linear morphea, and deep morphea. Mixed forms with different types of localized scleroderma occurring at the same time are observed in about 15% of patients. The most common form of localized scleroderma is an isolated circular patch of thickened skin called *plaque morphea* (Figure 84-17A and B). The histology is characterized by mononuclear cellular infiltrates (particularly during active phases) and deposition of thick bundles of collagen. It is usually confined to the dermis, but occasionally it can present with local panniculitis or deeper fibrosis. Multiple morphea lesions (*generalized morphea*) can involve extensive areas of the skin surface and occasionally can coalesce, mimicking the skin changes of systemic sclerosis (Figure 84-17D). In some cases, the morphea lesions may appear nodular and resemble keloids (*keloid morphea*) or, rarely, may form subepidermal bullae (*bullous morphea*) (Figure 84-17C). Inactive morphea may appear as flat areas of hyperpigmented

Figure 84-17 Localized scleroderma. **A**, Plaque morphea active and **(B)** inactive. **C**, Keloid morphea. **D**, Generalized morphea. **E**, Linear scleroderma affecting a lower limb and **(F)** the face (en coup de sabre).

skin. Active plaque morphea lesions present as enlarging geographic lesions with raised violaceous borders and ivory-white sclerotic centers. Localized scleroderma can also present as a linear streak (*linear scleroderma*) that crosses dermatomes and is associated with tracking of fibrosis from the skin into deeper tissues, including muscle and fascia (Figure 84-17E). In severe cases, linear scleroderma causes dramatic growth deformities of bone and supporting tissues in the affected regions. Linear scleroderma that affects the face and/or scalp associated with atrophy of muscle, underlying bone, and, rarely, brain tissue is called *en coup de sabre* (“sword stroke”) lesion (Figure 84-17F). Progressive hemifacial atrophy (Parry-Romberg syndrome) presents with atrophy of subcutaneous tissue, muscle, and bone without skin fibrosis. A close relationship among seizures, central nervous system (CNS) abnormalities, and ocular malfunction has been noted among these subtypes. Fasciitis with deep subcutaneous sclerosis can be seen in association with morphea lesions. *Pansclerotic morphea* is an uncommon but aggressive and disabling type of localized scleroderma that follows a progressive course despite treatment. It involves skin and deep tissues mimicking systemic sclerosis, but typically it spares the distal portion of the extremities, and the distribution of fibrosis acquires a “tank top” pattern on the trunk.

Although localized scleroderma may be disfiguring and disabling, it is generally a self-limited process that is not associated with a systemic illness. Patients with localized scleroderma have antinuclear antibodies most often directed against histones, chromatin, or nucleosomes, suggesting the presence of a specific underlying autoimmune process. Recent studies suggest that a combination of systemic corticosteroids and methotrexate can be effective treatment for localized scleroderma. Uncontrolled trials of topical therapy with ultraviolet (UV)A-1 phototherapy suggest that this treatment can be helpful for morphea lesions.

MIMICS OF SCLERODERMA

Several conditions that present with various degrees of skin fibrosis can be potentially confused with scleroderma (Table 84-7).¹⁵³ These disorders have different origins and exhibit distinct clinical characteristics, skin pathology, and disease associations. They often are detected in the primary care setting, and patients are referred to rheumatologists for further evaluation.

In the early 19th century, many cases of *scleredema* were mistakenly thought to be scleroderma. Scleredema is characterized by thick, indurated skin secondary to collagen and mucin deposition that normally begins on the trunk, especially over the upper back and shoulders, and can spread to arms, legs, and face. Scleredema occurs in the setting of three associated conditions: It can be a transient clinical manifestation following infection; a more persistent disorder associated with insulin-dependent diabetes; or an idiopathic process associated with a monoclonal gammopathy. It is seen in 2% to 15% of diabetic patients, particularly among those with poorly controlled disease. The course of scleredema varies with the underlying associated condition. It tends to resolve in several months when secondary to an infection, and it is improved with control of the diabetic state. No therapy has proved effective, but

Table 84-7 Spectrum of Scleroderma-like Fibrosing Skin Disorders

Immune-Mediated/Inflammatory
Eosinophilic fasciitis
Graft-versus-host disease
Lichen sclerosus et atrophicus
POEMS syndrome
Overlap (systemic lupus erythematosus, dermatomyositis)
Metabolic
Phenylketonuria
Porphyria cutanea tarda
Hypothyroidism (myxedema)
Deposition
Scleromyxedema
Systemic amyloidosis
Nephrogenic systemic fibrosis (or nephrogenic fibrosing dermopathy)
Scleredema adultorum
Lipodermatosclerosis
Occupational
Polyvinyl chloride
Organic solvents
Silica
Epoxy resins
Genetic
Progeroid disorders (progeria, acrogeria, Werner's syndrome)
Stiff skin syndrome (or congenital fascial dystrophy)
Toxic or iatrogenic
Bleomycin
Pentazocine
Carbidopa
Eosinophilia-myalgia syndrome (L-tryptophan)
Toxic oil syndrome (aniline denaturated rapeseed oil)
Postradiation fibrosis

POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

Adapted from Boin F, Hummers LK: Scleroderma-like fibrosing disorders, *Rheum Dis Clin North Am* 34:199–220, 2008.

UVA-1 treatment or PUVA (phototherapy) is reported to be of benefit.

Eosinophilic fasciitis (EF), also called diffuse fasciitis with eosinophilia or Shulman's syndrome or fasciitis-panniculitis syndrome, can also mimic scleroderma. Eosinophilic fasciitis is more common in males and presents as rapid and progressive stiffening of the arms, legs, and trunk. Inflammation and fibrosis within fascia create puckering of the skin and deep venous tracks (the “groove sign”). Because the inflammatory process is deep to cutaneous tissues, the superficial layers of the skin may be pinched readily in EF, in contrast to the thickened dermis involved in scleroderma. EF spares the fingers, is not associated with RP or nail-fold capillary abnormalities, and is not associated with systemic manifestations.¹⁵⁴ Peripheral eosinophilia is present in about 80% of cases but is not required to make a diagnosis. EF associates with a number of hematologic disorders, including immune-mediated anemia or thrombocytopenia, pure red-cell aplasia, myelodysplastic syndromes, and lymphoproliferative processes (T or B cell lymphoma, multiple myeloma). A diagnosis is made by clinical examination and by full-thickness biopsy that includes the fasciae. EF generally responds to corticosteroid therapy

and can completely resolve over several months. However, a small percentage of patients will have progressive, nonreversible disease.

Scleromyxedema (papular mucinosis) closely mimics the cutaneous manifestations of scleroderma. The skin has a flesh-colored papular eruption, giving it a cobblestone feel to light palpation. Distribution is typical with particular involvement of the glabella, posterior auricular area, and neck. The skin of the trunk and limbs also can become involved. Patients usually are between 30 and 70 years old and have an associated monoclonal gammopathy that usually is of the IgG type with lambda light chains. The presence of RP, sclerodactyly, esophageal dysmotility, pulmonary hypertension, and a myopathy can mimic features of scleroderma. Nail-fold capillary changes do not occur, and neurologic complications with encephalopathy, seizures, coma, and psychosis are reported. Scleromyxedema responds rapidly to treatment with intravenous immunoglobulin, but maintenance therapy must be continued to prevent relapse.¹⁵⁵

Nephrogenic systemic fibrosis (NSF) is a fibrosing disorder that occurs in patients with end-stage renal failure usually on chronic dialysis or following recent renal transplantation.¹⁵⁶ NSF usually develops over a short time (days to weeks) and then follows a chronic progressive course. This disorder is characterized by thickened, hardened skin with brawny hyperpigmentation and raised plaques, and then loss of limb function due to contractures secondary to subacute and chronic fibrosis of the skin, fasciae, and muscles. The face is usually spared. Deep fibrosis leads to flexion contractions and skin ulcerations. It is now clear that exposure to gadolinium-containing contrast agents in the setting of renal impairment triggers the disease process. Gadolinium deposits are found in involved tissues. By routine microscopy, findings range from a very subtle proliferation of dermal fibroblasts in early lesions to a florid proliferation of fibroblasts and dendritic cells in fully developed cases. Although it has been suggested that improvement can occur with improved renal function, no effective therapy has been confirmed. Reports of benefit with the use of imatinib mesylate are encouraging, but aggressive physical therapy, care to prevent skin ulcerations, pain control, and emotional support are the mainstay of therapy.

Scleroderma-like skin changes have been reported in a number of other disorders, including the carcinoid syndrome, chronic graft-versus-host disease, porphyria cutanea tarda, POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and scleroderma-like skin changes), bleomycin exposure, Werner's syndrome, and phenylketonuria. Eosinophilia-myalgia syndrome and toxic oil syndrome are conditions of historic interest resulting from ingestion of toxic contaminants and presenting with scleroderma-like features.

KEY POINTS

Myopathies are a heterogeneous group of muscle diseases characterized by symmetric proximal muscle weakness and frequent involvement of other organs.

Myopathies are often accompanied by elevated levels of serum muscle enzymes and abnormal electromyograms.

Histology shows varying degrees of inflammation and muscle fiber degeneration and regeneration.

Some patients have autoantibodies that bind to molecules involved in protein synthesis, and these antibodies are often associated with distinct clinical phenotypes.

Corticosteroids and cytotoxic drugs are common therapies.

HISTORY OF INFLAMMATORY MUSCLE DISEASES

Inflammatory muscle diseases are a heterogeneous group of systemic autoimmune rheumatic disorders characterized by chronic muscle weakness, muscle fatigue, and mononuclear cell infiltration into skeletal muscle. These disorders were described in the literature more than a century ago as generalized muscle disorders affecting principally the trunk and proximal limb muscles, with or without skin involvement.¹⁻⁵ It was also recognized that these diseases can range from acute and even fatal to slow, progressive, chronic, insidious conditions, with patterns of relapse and remission. Steiner's⁶ summary of myositis cases in 1903 made a clear distinction between idiopathic polymyositis (PM) and other forms of myositis caused by bacteria and parasites,⁶ and Stertz⁷ in 1916 first reported an association between dermatomyositis (DM) and internal malignancy.⁷ At about the same time, Batten⁸ described the first case of DM with classic histologic features in a child.

Since the 1940s, it has been recognized that PM may occur in the absence of cutaneous lesions, muscle pain, or constitutional symptoms. It may present in an acute, subacute, or chronic insidious form, with some fraction of cases showing systemic features or involvement of organs and tissues.⁹ The differential diagnosis has been described independently by several investigators, and the most chronic form was differentiated from an adult variety of muscular dystrophy.¹⁰⁻¹² Banker and Victor¹³ noted that DM in children was different and involved a greater degree of vascular inflammation and thrombosis (systemic angiopathy). The first, and still widely used, classification scheme and set of diagnostic criteria for myositis were proposed by Bohan and Peter in 1975.^{14,15} They include PM and DM but not the later-described subset known as inclusion body myositis

Inflammatory Diseases of Muscle and Other Myopathies

KANNEBOYINA NAGARAJU •
INGRID E. LUNDBERG

(IBM). IBM was later defined by the presence of distinct histopathologic changes including vacuoles and nuclear and cytoplasmic inclusions, as well as by distinct clinical features including resistance to glucocorticoids.^{16,17} Debate continues whether IBM should be considered an idiopathic inflammatory myopathy (IIM). We have chosen to include information on IBM in this chapter because it is clinically relevant to the differential diagnosis of PM.

EPIDEMIOLOGY

The actual annual incidence of inflammatory myopathy is currently unknown. Because these diseases are so rare, no large-scale epidemiologic studies have been reported; however, several retrospective studies have reported an annual incidence of less than 10 per million individuals¹⁸⁻²² (Table 85-1). This may be an overestimate, given that the Peter and Bohan diagnostic criteria used in these studies did not distinguish IBM as a separate disease entity. The prevalence of IBM has been estimated to be 10.7 per million in the United States, 9.3 per million in Australia, and 4.9 per million in the Netherlands.²³⁻²⁵ The age-adjusted prevalence of IBM for those older than 50 years was reported as 16 to 35 per million.^{24,25} In some geographic areas, IBM appears to be the most common acquired progressive myopathy, representing 16% to 28% of all inflammatory myopathies.²⁵ There may be referral biases in these studies. The incidence-prevalence studies need to be interpreted cautiously, given that most have not reported confidence intervals for their rates.

The incidence of the various myopathies varies according to ethnicity, age, and gender. Some studies have reported that the incidence of PM is higher in black patients than in white patients.¹⁸ IIMs can occur in any age group, from early childhood to late in adult life. The onset of PM is usually in the late teens or older, with the mean age at onset being 50 to 60 years; DM shows two peaks—5 to 15 years and 45 to 65 years. IBM is commonly seen in individuals older than 50 years and is rare in younger adults. Some studies have reported gender-specific incidence rates. For example, in the case of PM and DM, females are more commonly affected than males (ratio > 2:1), whereas in IBM, the converse is true (again, >2:1 ratio).

Inflammatory myopathies can occur in association with other autoimmune connective tissue diseases such as scleroderma, systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren's syndrome, polyarteritis nodosa, and sarcoidosis. Significant proportions of all myositis patients (11% to 40%) have an associated connective tissue disease.^{23,26,27} Several studies have also confirmed an association between malignancies and inflammatory myopathies.

Table 85-1 Incidence of Inflammatory Myopathies by Country

Country	Study Dates	Incidence (million/yr)	Reference
United States	1963-1982	5.5	18
United States	1947-1968	5.0	20
Australia	1989-1991	7.4	21
Sweden	1984-1993	7.6	22
Israel	1960-1976	2.1	205

A 2-decade-long retrospective study of myositis patients revealed about 12% (37/309) of the patients are associated with malignant diseases. A majority (81%) (30/37) of these patients had DM, and the remainder (19%) had PM. In about 68% of these cases malignancy and myositis appeared within 1 year. The most frequent malignancies associated with myositis were breast tumors and adenocarcinomas, and successful treatment of the underlying malignant disease improved the clinical disease course of myositis. Overall survival rate was considerably worse for DM compared with other forms of myositis.²⁸ Similar observations were made in a nationwide cohort study in Taiwan that indicated although the general risk of cancer was increased in IIM patients, cancers of the nasopharynx, lung, and breast tissue were the most likely to be diagnosed in both PM and DM patients. Detection of malignancies most frequently occurred within 1 year of being diagnosed with an IIM, with the likelihood of developing a malignancy decreasing over time.²⁹ Overall, the frequency of malignancies varies widely (4% to 42%) in different studies,^{19,30} but in general the incidence of malignancy is higher in DM patients than in IBM or PM patients.³¹ It is difficult to determine the relative risks for a particular malignancy because a variety of malignancies are associated with myositis, and only small numbers of individual malignancies have been reported in any one study.

ETIOLOGY OF MYOSITIS

Genetic Risk Factors

An association with immune response genes and occasional reports of familial clustering of myositis support the role of genetic factors in these diseases.³²⁻³⁷ Polymorphisms in human leukocyte antigen (HLA) class I and II genes are known genetic risk factors for several autoimmune diseases including myositis, but the mechanisms for these associations remain unclear. One possibility is that because the gene products influence T cell repertoire development, tolerance, and immune responses to foreign agents, certain polymorphisms may be selected on the basis of environmental triggers. It appears that haplotypes HLA-DRB1*0301 and HLA-DQA1*0501 are the strongest known genetic risk factors for all forms of myositis in whites; however, different phenotypes have additional HLA risk and protective factors.^{37,38} It has been shown that in African-American patients neither DRB1*0301 nor DQA1*0501 is strongly associated with myositis. Instead, the HLA-DRB1*08 allele shows the highest general risk for developing myositis, whereas the HLA-DRB1*14 allele is strongly protective in African-American patients.³⁹ The HLA-B8/DR3/DR52/

DQ2 haplotype is found in a significant proportion of IBM patients.⁴⁰ The risk and protection conferred by HLA associations differ significantly among different ethnic and serologic groups. For example, in some populations (e.g., Koreans, Mesoamericans), there is no association with HLA genes.³⁵ Further, HLA-DRB1*0301, which is a risk factor in whites, is a protective factor in the Japanese population.⁴¹ The HLA-DRB1*0301, HLA-DQA1*0501, and HLA-DQB1*0201 alleles are strongly associated with myositis-specific antibodies in PM patients.⁴² Mechanistic data supporting the role of HLA molecules in disease pathogenesis are, unfortunately, lacking at present. Some studies have reported that maternally derived chimeric cells are present in the peripheral blood and muscle tissues of juvenile DM patients, suggesting that HLA alleles control the occurrence of chimerism and explain the HLA association found in these disorders.^{43,44} Like other autoimmune disease conditions, myositis is a complex multigenic disorder involving other non-HLA immune response genes (e.g., cytokines and receptors including tumor necrosis factor [TNF], interleukin [IL]-1, and tumor necrosis factor receptor [TNFR]-1); complement components (e.g., C4, C2); immunoglobulin heavy-chain allotypes, and T cell receptors.⁴⁵ The exact contribution of the genetic component in these disorders is currently unknown, in part because of their rarity, the small number of subjects in any single cohort, and the heterogeneity in disease phenotype. International collaborative efforts are currently under way to address these issues and to identify potential genetic and environmental risk factors in myositis.

Environmental Risk Factors

The temporal association of myositis onset and environmental agents in certain individuals suggests that specific exposures in the context of certain genetic backgrounds can initiate muscle inflammation. Common environmental agents implicated in myositis include infectious organisms such as viruses and bacteria and noninfectious agents such as drugs and food supplements (Table 85-2). For example, enteroviruses (influenza, coxsackievirus, echoviruses) and retroviruses (human T-lymphotropic virus-I) are known to induce muscle inflammation. The myositis associated with enteroviruses usually occurs in children and is generally self-limited. A viral cause is strengthened by the presence of high-titer antiviral antibodies and viral particles in patients' serum and tissue samples,^{46,47} as well as the induction of muscle inflammation by enteroviruses in animal models. Attempts to identify virus in the tissues of IIM patients by sensitive techniques such as polymerase chain reaction have failed, leading to doubts about the viral cause of these diseases⁴⁸ and ruling out continual viral infection as a cause of the ongoing muscle inflammation in these patients. However, it is possible that viruses initially trigger the disease process before being eliminated by the host's immune response, thus explaining the absence of viral genomes in the myositis muscle tissue. Similarly, some microorganisms such as staphylococci, clostridia, and mycobacteria are known to affect skeletal muscle and cause acute muscle inflammation, but there is no evidence that these organisms actually cause chronic, self-sustaining muscle inflammation.

Table 85-2 Possible Environmental Risk Factors

Infectious Agents	
Viruses	
Picornavirus family, enteroviruses	
Polio, coxsackievirus types A and B, echoviruses	
Retroviruses	
HIV-1, HTLV-I	
Parvovirus B19	
Hepatitis C virus	
Hepatitis B virus	
Bacteria	
Staphylococci	
Clostridia	
Mycobacteria	
Parasites	
<i>Toxoplasma gondii</i>	
<i>Trypanosoma cruzi</i>	
<i>Borrelia burgdorferi</i>	
Noninfectious Agents	
Drugs	
D-Penicillamine	
Corticosteroids	
Chloroquine	
Statins (atorvastatin, lovastatin, pravastatin, simvastatin)	
Lipid-lowering fibrates (bezafibrate, clofibrate, gemfibrozil)	
L-Tryptophan	
Biologic agents (e.g., growth hormone, interferon- α , interleukin-2)	
Vaccination for tetanus, BCG, diphtheria, hepatitis B, hepatitis A	
Miscellaneous drugs (e.g., local anesthesia, hydroxyurea, leuprolide acetate)	
Ultraviolet radiation exposure	
Miscellaneous agents (e.g., silicone breast implants, chronic graft-versus-host disease associated with bone marrow transplantation, collagen injection, silica exposure)	

BCG, bacille Calmette-Guérin; HIV, human immunodeficiency virus; HTLV-I, human T-lymphotropic virus I.

Parasites such as *Toxoplasma gondii*, *Trypanosoma cruzi*, and *Borrelia burgdorferi* have been implicated in the triggering of IIMs. The evidence in support of a parasitic cause includes the recovery of parasites from some myositis patients and their serologic response to the parasites; improvement in myositis symptoms after treatment with antiparasitic drugs; a histologic picture of inflammation including infiltration of macrophages and CD4 T cells; and induction of myositis after parasitic infection in animal models.⁴⁹⁻⁵⁵ Despite these observations, it is difficult to establish a direct link between any parasitic infections and myositis in human patients because there is often no history of antecedent parasitic infection.

Ultraviolet (UV) light irradiation is likely to be a risk factor for the development of DM because epidemiologic data have demonstrated a latitude gradient of PM and DM, with the latter being more frequent closer to the equator and the former being more frequent in northern countries. The ratio between PM and DM is associated with a latitude gradient and is directly correlated with UV light irradiation. This observed correlation is particularly strong in a subset of DM patients with anti-Mi-2 autoantibodies, indicating that UV light may be an environmental risk factor for its development. The association between UV light exposure and subtype of myositis suggests that UV light is an exogenous modifier that can influence the clinical phenotype in PM and DM.⁵⁶

It appears that malignancy is an additional risk factor for the development of myositis, and there is a strong association between DM and malignancies. This early clinical observation has been confirmed in epidemiologic studies.^{30,57} With regard to PM and IBM, the association with malignancy is less convincing. The increased risk of malignancy associated with DM has been established both at the time of DM diagnosis and more than 10 years after diagnosis. The pathophysiologic mechanism for the association between malignancy and DM has not been clarified, but there could be several explanations. The strong association between malignancy and the onset of DM indicates that the latter could be a paramalignant phenomenon; that is, the development of myositis is a consequence of the malignancy (related to autoantigens), or the malignancy and DM share disease mechanisms. Thus the molecular mechanisms underlying this unique association are currently unclear. However, there is some evidence that removal of a tumor sometimes results in amelioration of muscle weakness, and tumor reappearance sometimes coincides with muscle weakness, suggesting that these two are linked.²⁸ A recent report has shed some light on this connection by showing that myositis-specific antigens are highly expressed in cancer tissues, as well as in regenerating muscle cells of myositis patients.^{58,59} The authors propose that in cancer-associated myositis, an autoimmune response directed against cancer cross-reacts with regenerating muscle cells, enabling a feed-forward loop of tissue damage and antigen selection.⁶⁰ This association must be explored further because cancer-associated myositis patients almost never develop myositis-specific autoantibodies, which are protective for the development of cancer. For malignancies that develop during established disease, the potential explanations include the presence of chronic inflammation or prolonged immunosuppressive treatment, which could contribute to the development of malignancy.

A recent report noted a novel association of myositis with hypertension, diabetes, and ischemic heart disease. The prevalence of hypertension and diabetes in this population was 62% and 29%, respectively, considerably higher than the background prevalence of 9.4% and 4%. These authors suggest that hypertension and ischemic heart disease were more likely to be present before the diagnosis of myositis, whereas hypertension and diabetes occurred more frequently following the diagnosis of myositis in DM patients in comparison with PM or IBM patients, suggesting that it is essential to perform a comprehensive assessment of vascular risk factors in these patients.⁶¹ The same group also reported that patients with IIM are at 75% increased risk for mortality, and cardiovascular diseases followed by infection and malignancy account for the commonest causes of death.⁶²

Mimics of Myositis

A variety of insults induce the clinical and pathologic spectrum that mimics myositis in some individuals (see Table 85-2). A number of drugs are known to cause a myopathy that closely mimics myositis. For example, D-penicillamine causes clinically and histologically indistinguishable IIM.⁶³ Likewise, commonly used lipid-lowering drugs such as statins (e.g., atorvastatin, lovastatin) can cause a

myopathy that resembles inflammatory myositis. These agents inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, a rate-limiting enzyme involved in the conversion of HMG-CoA to mevalonic acid, thereby preventing the synthesis of bioactive sterol and nonsterol metabolic intermediates in the cholesterol synthetic pathway. The mechanism by which these drugs cause myopathy is not clear yet.^{64,66} However, a recent study showed anti-HMGCR antibodies in patients with statin-induced autoimmune myopathy. It has been suggested that statins upregulate HMG-CoA autoantigen in regenerating muscle cells that in turn sustain an autoimmune response even after statin withdrawal, providing a mechanism for statin-induced immune-mediated necrotizing myopathy.⁶⁷ Other drugs such as hydroxyurea can cause skin rashes that resemble DM.⁶⁸ TNF inhibitors have been associated with the onset of autoimmune diseases such as vasculitis and a lupus-like syndrome. Recent reports implicate that TNF inhibitors in inflammatory arthritis patients may either induce or exacerbate DM or anti-Jo-1 positive PM.^{69,70} Some other reports point to the vaccine adjuvant aluminum hydroxide as a cause of macrophagic myofasciitis. The histology shows infiltration by macrophages and some CD8⁺ T cells into the endomysium, perimysium, and epimysium, together with clinically elevated creatine kinase (CK) levels, muscle weakness, myalgias, fatigue, and arthralgias.⁷¹ Despite some reports of vaccine-induced myositis, systematic investigation has failed to link any vaccine to myositis.⁷²

PATHOGENESIS

Significant advances have been made in our understanding of the pathogenesis of the human inflammatory myopathies.⁷³⁻⁷⁸ It is generally thought that IIMs are autoimmune in origin because they are frequently associated with other autoimmune diseases (e.g., Hashimoto's thyroiditis) and collagen vascular diseases (e.g., scleroderma); many patients exhibit an autoantibody response including the presence of myositis-specific autoantibodies; some studies provide evidence for lymphocyte-mediated muscle fiber injury; and a favorable response to immunosuppressive therapies in some patients supports an autoimmune cause of these disorders.

Humoral Immune Response

More than 50% of all IIM patients have uniquely defined autoantibodies—some of which are specific to myositis, and some of which are merely associated with myositis. These are generally referred to as myositis-specific autoantibodies (MSAs) and myositis-associated autoantibodies (MAAs), respectively. MAAs include autoantibodies to various nuclear and cytoplasmic antigens. Antinuclear antibodies (ANAs) present in myositis are not particularly associated with any disease subgroup, whereas MSAs that are directed against antigens of the protein synthesis pathway (e.g., aminoacyl-transfer RNA [tRNA] synthetases and signal recognition particles) and nuclear components (e.g., nuclear helicase [Mi-2]) are often associated with distinct clinical disease groups and subgroups (e.g., tRNA synthetases with interstitial lung disease, Mi-2 with DM) (Table 85-3).

Table 85-3 Myositis-Specific Antibodies

Autoantibodies	Clinical Disease/Features
Antisynthetase autoantibodies*	More common in polymyositis than dermatomyositis; interstitial lung disease, arthritis, Raynaud's phenomenon, fevers, mechanic's hands
Signal recognition particle (SRP) [†]	Polymyositis; possible severe disease and cardiac involvement
Chromodomain helicase DNA binding proteins 3 and 4 (Mi-2α and β) [†]	Dermatomyositis

*Common antisynthetase antibodies found in myositis are targeted to histidyl-tRNA synthetase (Jo-1), threonyl-tRNA synthetase (PL-7), alanyl-tRNA synthetase (PL-12), isoleucyl-tRNA synthetase (OJ), glycyl-tRNA synthetase (EJ), and asparaginyl-tRNA synthetase (KS).

[†]Autoantibodies commonly bind to a 54-kD SRP protein in the U.S. patient population and 72-, 54-, and 9-kD proteins in the Japanese population.

[†]Targets a 240-kD helicase protein that is part of the nucleosome remodeling deacetylase complex.

Anti-histidyl-tRNA synthetase antibodies are the most frequent and are present in about 16% to 20% of myositis patients.⁷⁹⁻⁸¹ Antibodies against other aminoacyl-tRNA synthetases such as threonyl-tRNA synthetase (PL-7), alanyl-tRNA synthetase (PL-12), isoleucyl-tRNA synthetase (OJ), glycyl-tRNA synthetase (EJ), and asparaginyl-tRNA synthetase (KS) are found less frequently (1% to 3%). Anti-Mi-2 antibodies are strongly associated with DM,^{82,83} with prominent features such as Gottron's papules, heliotrope rash, the V sign, and the shawl sign. An individual usually has only one MSA because MSAs are often mutually exclusive. The MSAs are most common in patients with other autoimmune diseases and are infrequent or absent in IBM patients and those with malignancies, muscular dystrophies, or other myopathies. These antibodies are sometimes present before the onset of clinical disease.⁸⁴

MAAs such as PM-Scl are frequently associated with a characteristic overlap syndrome that includes features of scleroderma.^{85,86} This syndrome is characterized by mild muscle disease, prominent arthritis, and limited skin involvement; it frequently responds to therapy.⁸⁷ Some myositis patients also have other MAAs such as anti-snRNP, anti-Ro/SSA, anti-Ku, and anti-PMS1. Antibodies recognizing an uncharacterized 56-kD large nuclear ribonucleoprotein have been found in a majority of myositis patients (86%), and the antibody titer appears to vary with disease activity, suggesting its importance in our understanding of disease pathogenesis and its potential usefulness as a clinical disease marker.⁸⁸ Some of the MSAs show strong immunogenetic associations; for example, antibodies against aminoacyl-tRNA synthetases are associated with HLA-DQA1*0501, anti-SRP with DR5, anti-Mi-2 with DR7, and anti-PM-Scl with DR3.³⁷ Neither the molecular mechanisms that initiate and perpetuate the autoimmune response nor the precise role of these autoantibodies in the pathogenesis of myositis is currently known. However, these antibodies serve as excellent clinical markers and can help diagnose and categorize these heterogeneous disorders into homogeneous subgroups.

Cell-Mediated Immune Response

At the cellular level, there are distinct differences in the distribution and location of the various lymphocyte subsets in the muscle tissues in different IIMs. Two major patterns of inflammatory cell infiltrates are seen in muscle tissue. The first has a predominantly perivascular distribution (Figure 85-1A), often in perimysial areas (Figure 85-1C), and is largely made up of CD4⁺ T cells, macrophages, and dendritic cells. Occasionally, B cells are present in some patients. This pattern is seen mainly in DM patients with skin rash but occasionally in patients without a rash. The second pattern has a predominantly endomysial distribution (Figure 85-1B), with mononuclear inflammatory cells often surrounding and sometimes invading non-necrotic muscle fibers. These inflammatory cellular infiltrates are comprised primarily of CD8⁺ T cells and macrophages, but CD4⁺ T cells and dendritic cells are also present. This pattern is generally seen in patients without skin rashes and often in those classified as having PM or IBM. In some patients, the two patterns of inflammation are seen in the same biopsy. The two distinct locations and the varying compositions of the inflammatory cell populations in the two areas suggest two different pathogenic mechanisms—one that targets the blood vessels and one that targets the muscle fibers. Notable inflammation is also seen in other organs.

The vascular involvement in patients with DM is also manifested in the skin and can be seen clinically in the form of nail-fold changes and changes in the gastrointestinal (GI) tract. The capillaries show clear hyperplasia, vacuolization, and necrosis, contributing to an ischemia that could cause fiber damage.^{89,90} One of the earliest events in the pathogenesis of DM appears to be activation of the complement cascade. This leads to the subsequent deposition of complement components, which in turn results in

the deposition of lytic membrane attack complexes in the endothelial cells and the eventual loss of capillaries due to complement-mediated damage. The capillaries are abnormally thickened and enlarged and look like high endothelial venules, which are characteristics of vessels that facilitate lymphocyte trafficking (Figure 85-2). The capillaries also show signs of neovascularization.⁹¹ This loss of capillaries results in some of the histopathologic features characteristic of this disease: capillary necrosis and loss, perivascular inflammation and ischemia (rarely seen), and perifascicular atrophy (a late feature; see Figure 85-1C and D). Recent studies also point out a role for type I interferon (IFN)-inducible genes in the pathogenesis of DM. It has been shown that plasmacytoid dendritic cells produce type I IFN and induce expression of IFN-inducible proteins such as MxA and IFN-inducible gene 15 (ISG15) at perifascicular myofibers and capillaries of DM biopsies, suggesting that injury to muscle fibers and capillaries occurs due to the intracellular overproduction of one or more type I IFN-inducible proteins in DM.^{92,93} Although no direct comparison has been reported, the pathologic changes in juvenile and adult DM appear to be similar, except that all the basic pathologic features are more prominent in the childhood form (see later). The factors that initiate complement activation in this disease are poorly understood; however, the consequences of complement-mediated damage are clearly visible in DM.⁹⁴

The endomysial inflammatory aggregates contain a high percentage of T cells, particularly activated CD8⁺ T cells, macrophages, and CD4⁺ T cells and few natural killer cells. Immunoelectron microscopic studies have provided evidence of the invasion, replacement, and probable destruction of non-necrotic muscle fibers by T cells and macrophages.⁹⁵ It is suggested that CD8⁺ cytotoxic T lymphocytes (CTLs) recognize major histocompatibility

complex (MHC) class I on muscle fibers and may mediate muscle fiber damage. Infiltrating CTLs express perforin-containing granules, which are characteristically oriented toward the target muscle fiber, indicating that muscle fiber injury may be partially mediated by perforin-dependent cytotoxic mechanisms (Figure 85-3B and C).⁹⁶ In PM and IBM, there is evidence of clonal proliferation of CD8⁺ T cells, both within the muscle and in the peripheral circulation.^{97,98} T cell lines from patients demonstrate cytotoxicity against autologous myotubes,⁹⁹ suggesting that the muscle fiber injury in PM and IBM is mediated by CTLs. CTLs are known to mediate target cell damage by both perforin-granzyme B and Fas-FasL pathways. The overexpression of antiapoptotic molecules such as Bcl-2, Fas-associated death domain–like IL-1 converting enzyme inhibitory protein (FLIP), and human inhibitor of apoptosis protein–like protein in skeletal muscle of myositis patients suggests that perforin-granzyme B–mediated CTL damage may play a predominant role in muscle fiber injury and dysfunction in myositis.¹⁰⁰⁻¹⁰²

In contrast to previous concepts, recent studies also show accumulations of B cells, plasma cells, myeloid dendritic cells, late-activated macrophages expressing 25F9 marker, as well as CD8⁺ CD28[−] and CD4⁺ CD28[−] T cells (TCR V[β]-expanded T cells) in the skeletal muscle and in the peripheral circulation of PM, DM, and IBM patients. These CD28[−] cells and late-activated macrophages expressing 25F9 marker are hypothesized to exhibit cytotoxic potential and produce proinflammatory cytokines in IIM skeletal muscle.^{103,104} Another study also explored the potential role of FOXP3⁺ Treg cells in the pathology of myositis. These authors reported that the number of Treg cells correlated with the degree of inflammation in IIMs and suggested that these cells might serve to counterbalance activity of cytotoxic T cells in myositis.¹⁰⁵

On the basis of the data described, two different pathways have been proposed as major mediators of muscle damage and inflammation: one mediated through T lymphocytes (CTLs) directed against muscle fibers, predominating in PM and IBM, and the other directed against

Figure 85-3 HLA-ABC, CD8⁺ T cell, and granzyme B staining of polymyositis biopsy. HLA expression is evident on muscle fibers, infiltrating cells, and endothelial cells (A). HLA cell surface and sarcoplasmic staining is shown on muscle fibers (B), CD8⁺ T cells (C, arrow), and granzyme B–positive cells (D) surrounding muscle fibers (arrow).

vessels, predominating in DM. However, several studies have shown that the degree of inflammation does not consistently correlate with the severity of the structural changes in the muscle fibers or with the severity of the clinical disease,¹⁰⁶ suggesting that nonimmune processes also play a role in disease pathogenesis. A role for nonimmune processes is supported by the following observations: First, marked structural changes in the muscle fibers occur in the absence of any inflammatory cells.^{107,108} Second, there is a lack of correlation between the degree of inflammation and the degree of muscle weakness.¹⁰⁹ Third, some myositis patients do not respond, even to powerful anti-inflammatory therapy.^{110,111} Fourth, steroid treatment may eliminate inflammatory cells in myositis muscle tissue, but this removal alone may not substantially improve the clinical disease, suggesting that immunosuppressive therapies modulate disease activity but do not change other mediators of the disease process.¹¹² Finally, the clinical disease may progress when identifiable inflammation has subsided,¹¹³ suggesting a role for nonimmune mechanisms in the pathogenesis of myositis. Thus the exact contribution of immune-mediated pathways to muscle damage is currently unknown.

Class I Major Histocompatibility Complex

Normal skeletal muscle cells do not constitutively express or display MHC class I molecules, although they can be induced to do so by proinflammatory cytokines such as IFN- γ or TNF^{107,114-116} or by the alarmin HMGB1.¹³⁹ In contrast, in human IIMs, the early and widespread appearance of MHC class I in non-necrotic muscle cells is a striking feature, even in muscle cells distant from the lymphocytic infiltration.^{107,108,117} MHC class I staining is usually observed on the sarcolemma of muscle fibers, but some fibers also show staining in both the sarcolemma and the sarcoplasm (see Figure 85-3A and B). In some patients, the expression is restricted to a few clusters (often in early disease), whereas in others, almost every fiber is positively stained, particularly in late-phase and treatment-resistant cases. The biologic significance of these observations has been explored by generating a conditional transgenic mouse model overexpressing syngenic mouse MHC class I. The overexpression of MHC class I molecules in the skeletal muscle of mice results in the development of clinical, biochemical, histologic, and immunologic features that resemble human myositis and provides a close model of the human disease. The disease in these mice is inflammatory, limited to skeletal muscles, self-sustaining, more severe in females, and often accompanied by MSAs.¹¹⁸ Recent studies in this model further suggest that MHC class I overexpression leads to endoplasmic reticulum stress, muscle atrophy, and decrease in force generation capacity of skeletal muscle, implicating the role for MHC class I muscle weakness in myositis.^{119,120}

A number of observations in human myositis patients and in the mouse model of myositis suggest that MHC class I molecules themselves may mediate muscle fiber damage and dysfunction in the absence of lymphocytes. For instance, in human myositis, the induction of MHC class I antigen in muscle fibers occurs early, preceding inflammatory cell infiltration.^{121,122} MHC class I staining of human myositis biopsies shows both a cell surface and a sarcoplasmic

reticulum pattern of internal reactivity, demonstrating that some of the MHC class I molecules may be retained in the endoplasmic reticulum (ER) of these fibers.^{78,108,123} Persistent MHC class I overexpression in muscle fibers may exist in the absence of an inflammatory infiltrate.¹¹³ The controlled induction of MHC class I in the mouse model is followed by muscle weakness before mononuclear cell infiltration.¹¹⁸ It has recently been shown that *in vivo* gene transfer of MHC class I plasmids attenuates muscle regeneration and differentiation.¹²⁴ Together, these observations, and particularly the obvious retention of MHC class I within the cell in both human and murine disease, indicate that the muscle fiber damage seen in myositis may not be solely mediated by immune attack (e.g., CTLs, autoantibodies); it may also be mediated through nonimmunologic mechanisms such as the ER stress response and hypoxia.

Because MHC class I assembly occurs in the ER and because upregulation in myositis muscle fibers is widespread, even in the absence of visible inflammatory infiltrate, it is likely that ER stress plays a role in the muscle fiber damage and dysfunction associated with human myositis. The ER is intimately involved in the folding, exporting, and processing of newly synthesized proteins. When there is an imbalance between the protein load in the ER and the cell's ability to process that load, a series of signaling pathways that adapt cells to ER stress is activated. This ER stress response can be provoked by a variety of pathophysiologic conditions including ischemia, hyperhomocysteinemia, viral infections, and mutations that impair protein folding, as well as by excess accumulation of protein in the ER.^{125,126} Cells self-protect against ER stress by initiating at least four functionally distinct responses: (1) upregulation of the nuclear factor κ B (NF κ B) pathway (ER overload response); (2) upregulation of genes encoding ER chaperone proteins such as Bip/GRP78 and GRP94, as a means of increasing protein folding activity and preventing protein aggregation; (3) translational attenuation to reduce the load of protein synthesis and to prevent the further accumulation of unfolded proteins (unfolded protein response); and (4) cell death, which occurs when the ER's functions are severely impaired. This cell death event is mediated by transcriptional activation of the gene for CHOP/GADD153, a member of the C/EBP family of transcription factors,¹²⁷ and by the activation of ER-associated caspase 12.¹²⁸

In myositis, it appears that overexpression of MHC class I in myofibers initiates a series of cell autonomous changes that contribute to myofiber pathology. Recent investigations have indicated that overexpression of MHC class I on muscle fibers results in activation of the NF κ B and ER stress response pathway in human inflammatory myopathies and in the mouse model of myositis.^{78,129} NF κ B can be activated within minutes by a variety of stimuli including inflammatory cytokines such as TNF and IL-1, T cell activation signals, and stress inducers. It is likely that in human myositis, NF κ B activates both classic (proinflammatory cytokines) and nonclassic (ER stress response) pathways.^{78,129-132} Further, there is evidence that downstream target genes (e.g., MHC class I, intercellular adhesion molecule [ICAM], monocyte chemoattractant protein [MCP]-1) regulated by the NF κ B pathway are highly upregulated in myositis patients.^{123,133,134} Recent studies have indicated that NF κ B p65 is activated both in human myositis biopsies and in the

Figure 85-4 Nuclear factor κ B (NF κ B) expression in normal and myositis biopsy. Immunofluorescence staining with rabbit anti-NF κ B and anti-rabbit Texas red and counterstaining with 4, 6-diamino-2-phenylindole (blue nuclei). Note the cytoplasmic expression of NF κ B in normal muscle (**A**) and a subsarcolemmal pattern in the myositis biopsy (**B**; arrow). (From Nagaraju K, Casciola-Rosen L, Lundberg I, et al: Activation of the endoplasmic reticulum stress response in autoimmune myositis: potential role in muscle fiber damage and destruction, *Arthritis Rheum* 52:1824–1835, 2005.)

mouse model,^{78,129,135,136} suggesting that this pathway may be directly involved in muscle fiber damage (Figure 85-4). NF κ B is a potential therapeutic target in myositis, and the use of NF κ B pathway inhibitors significantly reduces the pathology associated with several autoimmune diseases including diabetes, multiple sclerosis, inflammatory bowel disease, and rheumatoid arthritis, suggesting that this pathway is a critical player in the effector phase of autoimmune pathology. Thus it appears that MHC class I expression on muscle fibers links the immune and nonimmune mechanisms of muscle fiber damage.

Cytokines and Hypoxia

A number of other effector molecules produced in muscle tissue by inflammatory cells, endothelial cells, and muscle fibers are thought to play a role in the pathogenesis of myositis.⁷⁵ Most of the data assembled relate to cytokines, but some data related to chemokines are also available. The most consistently demonstrated cytokines in muscle tissue from patients with IIMs are cytokines with proinflammatory properties: IL-1 α , IL-1 β , TNF, and IFN- α . Recently, IL-10, IL-13, epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), CCL3 (macrophage inflammatory protein [MIP-1 α]), CCL4 (MIP-1 β) and CCL11 (eotaxin), IL-15, and IL-15R α were also demonstrated to be significantly upregulated and granulocyte colony-stimulating factor (G-CSF) downregulated in patients with IIMs relative to normal subjects.^{137,138} Further, the DNA-binding high mobility group box 1 (HMGB1) was found to exhibit both extranuclear and extracellular patterns in the muscle tissue of patients with PM and DM. Stimulation with IFN- γ showed an increased HMGB1 expression in muscle nuclei and the myoplasm. Exposure to HMGB1 induced a reversible upregulation of MHC class I in the muscle fibers and irreversible decrease in Ca²⁺ release from the sarcoplasmic reticulum during fatigue, implicating a role of HMGB1 and MHC class I early in the pathogenesis of IIMs.¹³⁹ In addition to inducing the upregulation of MHC class I and II molecules on muscle fibers, cytokines may have a direct effect on muscle fiber function, as has been demonstrated for TNF.¹⁴⁰ The relative importance of the various cytokines and chemokines in patients with myositis is still uncertain, but these molecules

are potential biomarker candidates in this disease as exemplified by a recent study showing serum IL-6 production and the type I IFN gene signature in the peripheral blood correlating with disease activity in DM patients.¹⁴¹

Microvessel involvement was first observed in DM but has also become evident in PM. The endothelial cells in both subsets show increased expression of adhesion molecules and proinflammatory cytokines such as IL-1 α . This phenotype can be induced by tissue hypoxia, which may result from capillary loss and local tissue inflammation. Muscle tissue hypoxia can contribute to the clinical symptoms and muscle fatigue and might be associated with disease mechanisms in inflammatory myopathies.⁷⁵ A recent study reported the expression of VEGF receptor in muscle fibers and HIF-2 α reactivity in endothelial cells of PM and IBM patients. DM patients showed hypoxia-inducible factor (HIF)-1 α and HIF-1 β expression in endothelial cells, whereas expression of HIF-2 α , erythropoietin receptor, VEGF, and VEGF-R were also observed on muscle fiber. These observations suggest that deprivation of blood supply by immune-mediated mechanisms might trigger the upregulation of hypoxia-related proteins as an adaptive response.¹⁴² The hypoxia hypothesis is further supported by the clinical improvement observed after exercise, but a causal connection still needs to be established. In addition, magnetic resonance spectroscopic analysis, before and after a work load, has demonstrated reduced levels of energy substrates that are important for muscle contraction such as adenosine triphosphate and phosphocreatine, when compared with levels in healthy individuals. This finding supports the hypothesis that an acquired metabolic disturbance occurs in chronic inflammatory myopathies and that this disturbance can contribute to impaired muscle performance.

Proposed Mechanisms of Muscle Damage

Currently available data suggest that both immune (cell-mediated and humoral) and nonimmune (ER stress, hypoxia) mechanisms play a role in muscle fiber damage and dysfunction in myositis. ER stress, hypoxia, and the NF κ B pathway are highly active within the skeletal muscle of myositis patients, and the proinflammatory NF κ B pathway connects the immune and nonimmune components contributing to muscle damage. The relative contribution of

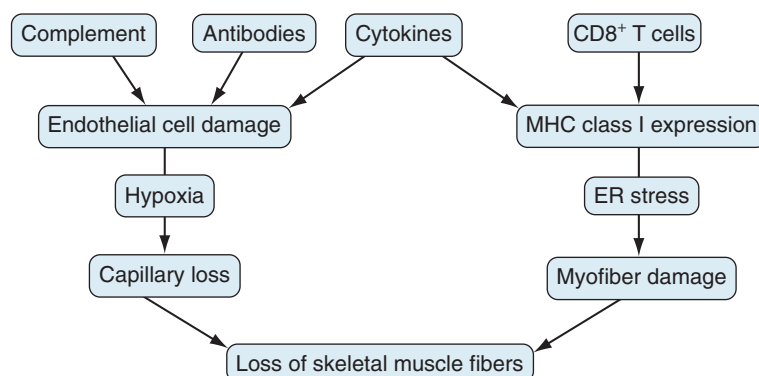

Figure 85-5 Mechanisms of muscle fiber damage in myositis. ER, endoplasmic reticulum; MHC, major histocompatibility complex.

each of these pathways to muscle fiber damage is presently unclear (Figure 85-5). Therefore use of specific drugs to inhibit these pathways, either alone or in combination, would help define their roles in myositis and potentially serve as effective therapeutic agents.

CLINICAL FEATURES

The inflammatory myopathies may occur as distinct disease entities, or they may coexist with some other rheumatic disease. This observation is true for all three subsets of myositis, but it is most often seen in PM and DM. The rheumatic diseases most often associated with inflammatory myopathies are systemic sclerosis, mixed connective tissue disease, Sjögren's syndrome, and SLE; however, rheumatoid arthritis may also be associated with inflammatory myopathies. IBM may be associated with Sjögren's syndrome, SLE, and other autoimmune diseases.^{143,144} Because the clinical features of IBM differ somewhat from those of PM and DM, they are presented separately.

Polymyositis and Dermatomyositis

The predominant symptoms in patients with PM or DM are muscle weakness and low muscle endurance. The weakness is most pronounced in proximal muscle groups—typically in the neck, pelvic, thigh, and shoulder muscles—with a symmetric distribution. Patients generally experience more problems performing repetitive movements than with single-strength exercises, and they report difficulty walking uphill or upstairs, working with their arms above their shoulders, or rising from chairs. The onset is often subacute, occurring over a few weeks, or it may be insidious, developing over several months. If untreated, the muscle weakness progresses slowly, and in the most severe cases, patients may become wheelchair dependent. Problems with swallowing and nutrition may occur as a result of impaired contractility of the throat muscles, possibly leading to aspiration pneumonia. In rare cases patients develop difficulty breathing because of weakness of the diaphragm or thoracic muscles, and they may require assisted ventilation. Other striated muscles may be involved, such as in the lower part of the esophagus (causing reflux problems) or the sphincter ani (causing incontinence).

Skin

Dermatomyositis is characterized by the presence of certain types of rashes¹⁴⁵; the same types are often seen in both children and adults. The most specific skin manifestations are Gottron's papules and the heliotrope rash (Figure 85-6). Gottron's papules are slightly elevated violaceous, pink, or dusky red papules located over the dorsal side of the metacarpal or interphalangeal joints. These papules may also occur over the extensor side of the wrist, elbow, or knee joints. Gottron's papules are considered to be pathognomonic of DM. A macular rash (without papules) with the same distribution as Gottron's papules is called *Gottron's sign* (see Figure 85-6C and D). The heliotrope rash is a periorbital red or violaceous erythema of one or both eyelids, often with edema (see Figure 85-6B). Linear erythema overlying the extensor surfaces of joints is also relatively specific to DM (Figure 85-7A). Many patients with DM have photosensitive rashes, typically located on the face or scalp or over the neck (the so-called V sign), although this rash is not specific to DM (Figure 85-7B and C). Another common rash in DM is located over the shoulders (shawl sign; Figure 85-7D) or over the hips (holster sign). Pruritus is common. Patients with DM often have skin lesions on their fingers such as periungual erythema, nail-fold telangiectasias, and cuticular overgrowth (Figure 85-8C). Other less common skin manifestations are panniculitis, livedo reticularis, and nonscarring alopecia. Vasculitis may be seen in children with DM but rarely in adults.

In general, the skin rash is moderate, with local erythema. In rare cases, a severe, diffuse erythema (erythroderma) may occur, occasionally with vesiculobullous lesions or ulcers. The skin rash may precede the muscle symptoms by months or even years, and in some patients, the skin manifestations may be the only clinical sign of DM; this condition is often called amyopathic DM or DM sine myositis (see later). The pattern of the rash over the knuckles and dorsum of the hand is distinct, in that the rash generally affects the phalanges but spares knuckles in SLE, and vice versa in DM (Figure 85-8A and B). However, no histopathologic skin features are specific for DM; most of the features are also seen in patients with SLE. Thus skin biopsy is rarely helpful in distinguishing between these two disorders. The cutaneous manifestations may fail to respond to

immunosuppressive treatment, despite improvement in muscle symptoms. Thus it is possible that different molecular pathways or disease mechanisms cause the skin rash and the muscle inflammation.

Calcinosis, which can be severe, is found mainly in juvenile DM but is occasionally seen in adults. The calcinosis occurs predominantly in sites that have been subject to friction or trauma such as the elbows or knees. Sometimes the calcinosis can be extensive and erupt, leading to ulcers. It is most often localized to the subcutaneous tissue but can also develop in the skin, fascia, or muscle and can be visualized by radiography, computed tomography (CT), or

magnetic resonance imaging (MRI). The calcinosis seems to progress as long as there is active inflammatory disease. Also, once it has developed, it is often treatment resistant. Some data, however, suggest that the progress of calcinosis can be inhibited by effectively treating the inflammatory process in the skin and muscle.¹⁴⁶

Another type of skin pathology seen in inflammatory myopathies is called mechanic's hands. This rash is often associated with the presence of antisynthetase autoantibodies and can be seen in both PM and DM. The rash is a hyperkeratotic, scaling, fissuring of the fingers, particularly on the radial side of the index fingers (Figure 85-9).

Lungs

Lung involvement is frequent in PM and DM and is a major risk factor for morbidity and mortality. Clinical symptoms such as dyspnea and cough are common. Lung involvement can be caused by weakness of the respiratory muscles or inflammation of the lung tissue (interstitial lung disease). Weakness of the respiratory muscles may lead to restrictive lung disease, and involvement of the pharyngeal muscles is a risk factor for aspiration pneumonia. Interstitial lung disease, caused by inflammation in the small airways, is common in PM and DM and is often associated with antisynthetase autoantibodies; it may be present in up to 70% of patients when investigated with sensitive techniques such as high-resolution CT and measurement of pulmonary function and diffusion capacity.¹⁴⁷ In most cases, the changes are present at the time of diagnosis of myositis; they rarely develop after immunosuppressive treatment has started. The severity of interstitial lung disease may vary from mild or even asymptomatic to rapidly progressive (Hamman-Rich-like) with a fatal outcome. In most cases, the interstitial lung disease is mild and has a slowly progressive course. In some cases, improvement in lung function is seen with immunosuppressive treatment. The course and outcome vary, depending on the histopathology, suggesting that different disease mechanisms cause interstitial lung disease.

In general, the clinical course and histopathology of interstitial lung disease in myositis are no different from

those in idiopathic interstitial lung disease. The most common histopathologic finding is nonspecific interstitial pneumonia, but other entities such as cryptogenic organizing pneumonia, bronchiolitis obliterans organizing pneumonia, diffuse alveolar damage, and usual interstitial pneumonia are also found. Some studies suggest that bronchiolitis obliterans organizing pneumonia responds favorably to corticosteroids, whereas histopathologic changes compatible with diffuse alveolar damage, usual interstitial pneumonia, or acute interstitial pneumonia respond poorly to corticosteroids or other immunosuppressive therapies and have a poor prognosis.

Arthritis

Joint pain and arthritis are common in patients with PM or DM. The most common form of arthritis is a symmetric arthritis of the small joints of the hands and feet. This arthritis is typically nonerosive but can sometimes be erosive and destructive. Most frequently, arthritis is seen in patients with anti-Jo-1 antibodies and other antisynthetase autoantibodies, but it is also seen in patients with overlapping syndromes of other rheumatic diseases.

Heart

Cardiovascular disease is a risk factor for death among patients with PM and DM. However, clinically evident heart involvement is rare, perhaps indicating that cardiac

Figure 85-9 Mechanic's hands in a white (**A**) and a black (**B**) patient. Note the characteristic skin changes on the lateral side of the fingers. (Courtesy Dr. Paul Plotz.)

involvement may be overlooked in these conditions. Subclinical manifestations are frequently discovered when patients with PM or DM are evaluated. The most frequently reported subclinical manifestations are conduction abnormalities and arrhythmias detected by electrocardiogram (ECG). The underlying pathophysiologic mechanisms that may lead to cardiac manifestations in patients with PM or DM are myocarditis and coronary artery disease, as well as involvement of the small vessels of the myocardium.

Examination with ECG is recommended in newly diagnosed patients with PM or DM. Serum tests such as CK-MB to detect cardiac involvement are unreliable in patients with inflammatory myopathies because CK-MB can be released from regenerating skeletal muscle fibers, a common feature in biopsies from patients with PM or DM. The CK-MB/total CK ratio may be greater than 3%, a threshold value that is used to define myocardial damage. A more specific marker for myocardial damage in myositis patients is increased serum levels of cardiac isoform troponin I. The other cardiac troponin isoforms, troponin C and troponin T, are less specific and are also expressed in adult skeletal muscle; increased serum levels have been reported in various muscle disorders.

Gastrointestinal Tract

Difficulty swallowing is frequent in patients with inflammatory myopathies, particularly those with IBM. Muscle weakness occasionally becomes severe and causes problems with nutrition and aspiration pneumonia. The pathophysiology is related to weakness in the tongue, pharyngeal muscles, and sometimes the lower esophagus. Reflux that requires special care is common, occurring in 15% to 50% of patients. Constipation, diarrhea, and stomach pain are common symptoms and may result from disturbed motility of the gut or GI tract inflammation. Vasculitis in the blood vessels of the GI tract is rare but may be complicated by intestinal bleeding.

Antisynthetase Syndrome

A new classification system is based on the presence of MSAs, rather than clinical and histopathologic changes. The most common of these antibodies are the antisynthetase autoantibodies directed against aminoacyl-tRNA synthetases. A clinically distinct subset of myositis, often called *antisynthetase syndrome*, has been identified in patients with antisynthetase autoantibodies.^{42,63} The most common of the antisynthetase autoantibodies is anti-Jo-1, which is directed against histidyl-tRNA synthetase. This autoantibody is present in approximately 20% of patients with PM or DM but is only rarely found in patients with IBM.⁷⁹ Antisynthetase syndrome is characterized by the presence of antisynthetase autoantibodies and a set of clinical features that includes myositis, interstitial lung disease, Raynaud's phenomenon, nonerosive symmetric polyarthritis of the small joints, and mechanic's hands (see Figure 85-9). These patients often have fever at disease onset and during flares of disease. Antisynthetase syndrome can be seen in patients with PM or DM but is more often seen in patients without skin rashes other than mechanic's hands.

Amyopathic Dermatomyositis

A subset of DM is called clinically amyopathic DM. These patients have a skin rash, which is typical of DM, but no clinical signs of muscle involvement.¹⁴⁸ The proposed definition is based on a skin biopsy consistent with DM and a duration of 6 months or longer in the absence of clinical or laboratory evidence of myositis. Some of these patients do have subclinical myositis based on MRI or biopsy findings at presentation; others develop clinically overt myositis sometime later. Patients without clinically overt myositis, however, may develop extramuscular manifestations such as interstitial lung disease, which may be severe. Amyopathic DM may be associated with malignancies, as is the case for classic DM. The frequency of this subset is uncertain, but some recent studies suggest that this form of DM may be more common than previously thought.

Juvenile Dermatomyositis

The incidence of juvenile dermatomyositis (JDM) is between 1.7 and 3 per million children. The disease onset has two peaks—at age 6 and 11 years. JDM is more common in girls than in boys in Europe and North America; in Japan and Saudi Arabia, this difference is less prominent. The most common clinical manifestations at disease onset are muscle weakness, easy fatigability, skin rash, malaise, and in some cases fever.¹⁴⁶ The skin rash is often pathognomonic and similar to adult DM, with the most typical skin manifestation being heliotrope discoloration of the upper eyelids, Gottron's papules, periungual erythema, and capillary loop abnormalities. Calcinosis, cutaneous ulceration, and lipodystrophy are more common in juvenile cases than in adults. Calcinosis is seen in 30% to 70% of children with JDM. The calcinosis is most often located at sites exposed to trauma and can be seen in the skin, fascia, or muscles. In some children, the calcinosis becomes prominent and causes contractures and ulcerations. Lipodystrophy occasionally develops, and other metabolic abnormalities such as insulin resistance and hepatomegaly are sometimes seen. Vasculopathy that affects the GI tract with ulceration, perforation, or hemorrhage is rare but seems to be more common in children than in adults with DM. Because this can be a serious sign, screening for GI involvement should be included in the evaluation of patients with JDM. Interstitial lung disease is rarely seen in JDM cases.

The overall prognosis is variable, but some patients have a good prognosis. Patients with JDM may go into remission, allowing the discontinuation of immunosuppressive treatment. Side effects of immunosuppressive treatment such as growth failure are common. In many patients, however, the disease remains chronic, with persisting disease activity into adulthood.

Inclusion Body Myositis

IBM is distinguished from PM and DM on the basis of both clinical and histopathologic features.^{149,150} Sporadic IBM is a distinct entity from familial hereditary inclusion body myopathy, which shares some clinical and histopathologic features but lacks signs of inflammation in muscle tissue.

Figure 85-10 Trichrome and hematoxylin and eosin staining of inclusion body myositis biopsy. Note the red-rimmed inclusions (**A**) and marked variation in muscle fiber size (**A** and **B**). (Courtesy Dr. Paul Plotz.)

IBM was identified in the 1960s as a subset of inflammatory myopathies, distinct from PM, primarily on the basis of typical histopathologic features that include sarcoplasmic and nuclear inclusions and rimmed vacuoles.^{16,17} A characteristic clinical phenotype was later identified, characterized by an insidious onset of muscle weakness over months to years, muscle weakness localized predominantly to the thigh muscles and finger flexors, and resistance to glucocorticoid treatment. IBM patients often have a history of frequent falling. Sporadic IBM cases are sometimes misdiagnosed as PM because the classic histopathologic changes (rimmed vacuoles and inclusions) may not be evident in early biopsies (Figure 85-10). A slowly progressive clinical course, development of severe muscle atrophy in the thighs and forearms, and resistance to treatment with immunosuppressive drugs should raise the suspicion of IBM, and a second muscle biopsy should be considered.

In contrast to PM and DM, IBM is more frequent in men than in women, and it is seen mainly in individuals older than 50 years. The onset is more insidious than that of PM or DM. Patients with IBM rarely have pain. The most frequent initial symptoms are difficulty climbing stairs and walking uphill and frequent falls as a result of weakness in the knee extensor muscles. Muscle weakness may become prominent, and even walking across a threshold may become a problem. Difficulty swallowing may also be an early clinical feature, reflecting the involvement of the pharyngeal muscles. The course is slowly progressive, leading to muscle atrophy that can be striking, particularly in the thigh and forearm muscles. Severe weakness may develop, and many patients become wheelchair dependent. Extramuscular organ involvement is rare, although a subgroup of patients with IBM has sicca symptoms and may develop a secondary Sjögren's syndrome.¹⁵¹ There are also occasional case reports of IBM in patients with other chronic inflammatory diseases such as SLE, systemic sclerosis, and interstitial pneumonitis. Autoantibodies are rarely present in IBM patients.

IBM is usually resistant to treatment with glucocorticoids and other immunosuppressive agents. Because of this resistance to treatment, some have questioned whether IBM is an autoimmune disease or a degenerative muscle disease supported by the abnormal accumulation of proteins such as amyloid- β in muscle fibers. This issue is still under debate and subject to ongoing research in several institutions around the world.

Myositis Associated with Malignancies

An association between DM and malignancies was observed in several early case reports. The clinical implications of this association, irrespective of the pathophysiologic mechanisms involved, are that it is imperative to screen for tumors in patients with DM at the time of diagnosis and at relapse, particularly if the symptoms do not respond to conventional immunosuppressive treatment. A myositis-specific autoantibody that is associated with DM and malignancies in adults, p155/140, has been identified, but its sensitivity and specificity in the context of myositis is not known.^{151a,151b} However, so far this autoantibody can only be detected by immunoprecipitation, which limits its use in clinical practice. The types of malignancies vary and include not only hematologic malignancies such as lymphoma but also solid tumors such as lung, ovarian, breast, and colon cancer. The screening for malignancies should include, at minimum, a careful clinical examination, routine blood tests, and chest radiograph. For women, mammography and a gynecologic examination should be conducted as well. If any abnormalities are found, these should guide a more thorough investigation for malignancies.

CLASSIFICATION AND DIAGNOSTIC CRITERIA

At present, there are no prospectively validated diagnostic or classification criteria for myositis. Dividing diseases into homogeneous subsets serves several important functions including allowing us to estimate disease incidence and prevalence, understand disease pathogenesis and natural history, and evaluate the patient's response to therapy and prognosis. More than 3 decades ago, Bohan and Peter^{14,15} proposed a set of five criteria to facilitate the diagnosis of IIM patients (Table 85-4). They classified IIMs into five groups: primary idiopathic PM, primary idiopathic DM, IIMs associated with malignancy, childhood IIMs associated with vasculitis, and IIMs associated with collagen vascular diseases. Exclusion criteria include signs of central or peripheral neurologic disease; family history of muscle disease (although familial myositis has been reported in dozens of cases); and symptoms and signs suggestive of muscular dystrophy, granulomatous myositis, infections (including trichinosis, schistosomiasis, trypanosomiasis,

Table 85-4 Bohan and Peter Criteria for Polymyositis and Dermatomyositis

Exclude all other myopathies
Symmetric proximal muscle weakness
Increase in serum muscle enzymes, such as CK, AST, ALT, aldolase, and LDH
Abnormal electromyographic findings, such as short, small, polyphasic motor units; fibrillations; positive sharp waves; insertional irritability; and bizarre high-frequency repetitive discharges
Abnormal muscle biopsy findings such as mononuclear infiltration, regeneration, degeneration, and necrosis
Skin rashes, such as heliotrope rash, Gottron's sign, and Gottron's papules

ALT, alanine transaminase; AST, aspartate transaminase; CK, creatine kinase; LDH, lactate dehydrogenase.

staphylococcal infection, and toxoplasmosis), drug-induced myopathy, toxic myopathy, rhabdomyolysis, metabolic disorders, endocrinopathies, myasthenia gravis, or myositis after viral infection (influenza or rubella). A weakness of the Bohan and Peter classification is that it overdiagnoses PM patients and loosely defines overlap syndromes.

Despite several drawbacks, these criteria have served well in diagnosing and defining patients for research purposes for the past 3 decades. IBM was later recognized as a separate disease entity characterized by a slow onset and progression involving finger flexors or the quadriceps muscles.^{149,150} It can occur as a stand-alone entity or with other connective tissue diseases, and patients are often resistant to steroid therapy. Other focal and diffuse forms of

myositis such as orbital myositis, focal nodular myositis, macrophagic myositis, and eosinophilic myositis are relatively rare.

Since Bohan and Peter proposed their classification criteria, advances in clinical research have led to the identification of certain autoantibodies that are strikingly associated with some clinical phenotypes of myositis (see Table 85-3). The identification of clinical features associated with MSAs and MAAs has led to the proposal of a serologic approach to complement the Bohan and Peter classification system. Others have suggested that the Bohan and Peter criteria be modified to add MSA as a criterion.¹⁵² However, the inclusion of MSA has some limitations: these antibodies are not present in all patients, the immunoprecipitation techniques that are the “gold standard” for identifying these antibodies are available in only a few commercial laboratories, and the enzyme-linked immunosorbent assays often used can give false-positive or false-negative results.

Ongoing debate and dialogue within the scientific community about the nature of the diagnostic and classification criteria that could better define these disorders is extensive.^{73,153,154} Some emphasize a focus on histopathologic features and others on autoantibody profiles. Certainly, the addition of autoantibody profiles, characteristic histopathologic and immunohistochemical features, and imaging techniques such as MRI would significantly strengthen the current criteria and better define these disorders. The most frequently used subclassification is based on differences in clinical, immunologic, and histopathologic features and identifies three subtypes of inflammatory myopathies: PM, DM, and IBM¹⁵⁵ (Table 85-5).

Table 85-5 Clinical and Laboratory Features of Idiopathic Inflammatory Myopathy Subgroups

Diagnostic Features	Dermatomyositis	Polymyositis	Inclusion Body Myositis
Clinical features			
Age	Children and adults	Adults ^a	Adults > 50 yr
Disease onset	Subacute	Subacute	Chronic
Muscle weakness	Proximal	Proximal	Selective pattern ^b
Symmetry	Symmetric	Symmetric	Asymmetric
Systemic features	Yes ^c	Yes ^c	Yes ^d
Skin changes	Yes ^e	No	No
Calcinosis	Yes ^f	Rarely	No
Associated connective tissue disease	Yes ^g	Yes ^g	Yes ^h
Associated malignancy ^j	Yes	Yes	Yes
Laboratory features			
Serum enzymes ⁱ	Normal to high	Normal to high	Normal to high
Abnormal EMG ^k	Yes	Yes	Yes
Abnormal muscle biopsy	Perifascicular atrophy, capillary depletion, patchy MHC class I expression and microinfarcts	CD8 ⁺ T cell invasion of non-necrotic fibers and MHC class I expression on fibers	CD8 ⁺ T cell invasion, MHC expression, vacuolated fibers, and tubulofilamentous inclusions in fibers

^aRarely in children.

^bEarly involvement of finger flexor, wrist flexor or wrist extensor weakness, and involvement of quadriceps femoris.

^cSome patients have dysphagia, synovitis, and interstitial lung disease.

^dSome patients have dysphagia.

^eGottron's sign and heliotrope rash.

^fEspecially in children.

^gOverlap with scleroderma, systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, and mixed connective tissue disease.

^hAssociated with Sjögren's syndrome but less frequently associated with other connective tissue diseases.

^jDermatomyositis is more frequently associated with cancer than are polymyositis and inclusion body myositis and not overrepresented in polymyositis or inclusion body myositis.

ⁱSerum creatine kinase, aspartate transaminase, lactate dehydrogenase, and aldolase vary from normal to very high levels.

^kMyopathic motor unit potentials with spontaneous discharges in dermatomyositis, with and without spontaneous discharges in polymyositis, and mixed pattern of short- and long-duration motor unit potentials in inclusion body myositis.

EMG, electromyogram; MHC, major histocompatibility complex.

PHYSICAL EXAMINATION

Although most patients present with muscle weakness or fatigue, the IIMs are systemic connective tissue diseases and other organs are frequently involved; therefore a full clinical examination should be conducted when patients present with muscle symptoms. This could also be helpful in distinguishing IIMs from noninflammatory myopathies.

The muscle problems reported by many patients consist of not only muscle weakness but also muscle fatigue or reduced muscle function. Thus the evaluation must differentiate between strength and fatigue by evaluating muscle strength and testing repetitive movements for muscle fatigue. In the early phases, atrophy is usually not a pronounced phenomenon in PM or DM. In later phases, a moderate symmetric atrophy of proximal muscles may be present. Asymmetric atrophies indicate conditions other than inflammatory myopathies. Patients with IBM often develop more severe atrophy of the quadriceps muscles and the flexor muscles of the forearms; they may also develop deformities in the finger joints and experience difficulty making fists.

Muscle strength can be tested in various ways. A quick screening test for weakness in proximal lower leg muscles is to ask the patient to stand up from a sitting or squatting position without support. A more standardized test that is easy to perform in the clinic is the manual muscle test, with grading according to the Medical Research Council (MRC) scale. There are many variants of this test, but a short form, addressing eight muscles on the dominant side, is recommended as part of the disease activity score by the International Myositis Assessment and Clinical Studies (IMACS).¹⁵⁶ In most patients with PM or DM, muscle strength as assessed by the manual muscle test is good in most of the tested muscle groups. Typically, moderate muscle weakness is seen in the neck flexors and hip girdle muscles. Testing that involves a number of repetitions is often a more sensitive method of detecting muscle impairment. The Functional Index in Myositis-2 is a myositis-specific outcome measure that assesses a number of repetitions. With this test, proximal muscle groups are more involved than are distal muscles. This index is often used by physical therapists.¹⁵⁷ In patients with IBM, knee extensors and finger flexors are often weak.

The skin should also be examined to detect changes including those in nail folds and the scalp. Joints can be affected by arthritis, and heart and lung changes should be carefully looked for.

LABORATORY EVALUATION

Laboratory evaluations are critical components of both diagnosis and patient management. Combinations of laboratory tests are generally used during patient evaluations. Because no laboratory test is highly specific for IIMs, the results of these tests are usually interpreted in the clinical context.

Biochemical

Measuring serum levels of muscle enzymes is an important part of the evaluation of myositis patients. Increased levels of muscle-derived serum enzymes reflect ongoing damage to

the muscle parenchyma. These measurements help differentiate IIMs from conditions such as steroid myopathy and denervation, in which atrophy is a prominent feature.¹⁵⁸ Measurement of the serum CK level is traditionally the first step in the assessment of patients with IIM. CK exists as MM (skeletal muscle), MB (cardiac muscle), and BB (brain) isoforms in serum. In comparison with other serum muscle enzymes, CK appears to be a relatively specific and sensitive indicator of the degree of muscle fiber injury. However, the range varies significantly among patients, with levels being near normal in some patients and elevated by several hundred-fold in others.

Generally, 80% to 90% of adult myositis patients show an increase in CK during the initial evaluation. However, a certain proportion of patients, especially those in advanced stages of the disease, show normal or relatively modest elevations in CK, in part because of a lack of muscle mass or the presence of inhibitors of CK activity.^{159,160} Normal CK is relatively more common in DM than in PM. In the absence of CK elevation, it is usually easier to diagnose DM than PM because of the presence of skin rashes in the former. It is also known that CK levels are generally lower in IBM patients than in those with PM or DM. Therefore a normal CK level does not exclude a diagnosis of IIM, particularly IBM or JDM.

Constantly elevated levels of CK are often a sign of inflammatory activity. A rise in CK level is generally correlated with overall disease activity over time, but not with strength or functional measures of disease activity.^{161,162} CK measurements are usually not useful for monitoring disease exacerbations, and they should always be evaluated in the clinical context. CK levels may normalize without clinical improvement, or they may increase without clinical worsening; however, increasing levels point to a potential flare and warrant closer clinical evaluation. CK elevations are not specific for myositis because this enzyme is also elevated in other muscle diseases including muscular dystrophies, rhabdomyolysis, hypothyroidism, and many drug-induced myopathies. It is important to note that serum levels of CK-MB can be elevated in patients with myositis as a result of the regeneration of skeletal muscle fibers; they are not specific for heart involvement in these patients. The cardiac isoform troponin I has the highest specificity as an indicator of myocardial involvement and is the most reliable serum marker for detecting myocardial damage in patients with inflammatory muscle disease.¹⁶³

Measurement of other serum muscle enzymes including aldolase, aspartate transaminase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH) significantly improves the chance of diagnosing myositis, especially in patients with active disease and normal CK levels. Aldolase, LDH, and AST are better correlated with disease activity in JDM patients. The main disadvantage of these enzymes is that they are also elevated in liver diseases; therefore the muscle source needs to be identified before interpreting the data.¹⁶⁴

The serum myoglobin level is a sensitive index of muscle fiber membrane integrity and can therefore be used to assess the degree of disease activity. The advantage of the myoglobin assay is that it involves a nonenzymatic immunologic reaction. Disadvantages are that a significant range of serum myoglobin levels occurs in myositis patients because of

circadian variation,¹⁶⁵ and the test is less readily available than CK for routine use. Elevation of other serum components such as troponin, creatine, neopterin, manganese superoxide dismutase, hyaluronate, and soluble CD30 has been shown to correlate with disease activity, but assays of these components have not been validated for use in clinical practice and they are not available for routine analyses.

Immunologic

The immune response to self-antigens is a common feature of several systemic autoimmune rheumatic diseases including IIMs. ANAs are found in approximately 60% to 70% of myositis patients. The autoantibody response in IIMs is directed to ubiquitous nuclear and cytoplasmic antigens. The presence of these antibodies is usually assessed by an indirect immunofluorescence assay. ANAs are more frequently found in patients with PM and DM, especially those with overlap syndrome. These are less frequently seen in IBM patients or those with malignancy-associated myositis. High-titer ANA is a particularly valuable finding for differentiating IIMs from dystrophies. Many IIM patients show speckled nuclear ANA patterns, and about 10% of IIM patients also show exclusive cytoplasmic patterns in indirect immunofluorescence staining.¹⁶⁶ Many of the MSAs are associated with distinctive clinical features such as skin rash or interstitial lung disease (Table 85-6). Certain MSAs such as anti-Jo-1 are more frequently associated with PM; others such as Mi-2 are more frequent in DM.

Histologic

Muscle biopsy is the “gold standard” for the diagnosis of inflammatory myopathies and a critical component of the definitive diagnosis of IIMs.^{167,168} For optimal biopsy results, it is important to select a muscle that is moderately weak. The histologic features can be grouped into general features that are common to all IIMs and specific features unique to a particular subgroup. The general features include necrosis,

regeneration, degeneration, variation in fiber diameter, increase in connective tissue, and inflammation. The features specific to DM include loss of capillaries, alterations in the morphology of capillaries, capillary necrosis with the deposition of complement products (e.g., membrane attack complex) on the vessel walls, and, rarely, muscle infarcts. Another specific histopathologic finding, albeit a late sign, is perifascicular atrophy. The infiltrates typically have a perivascular distribution. The inflammatory infiltrates are dominated by a high percentage of CD4 T cells and macrophages at the sites of inflammation, with B cells occasionally in evidence. Although perifascicular atrophy is the hallmark of the histologic changes seen in DM, it may not be visible if a biopsy is acquired early in the course of the disease. In early DM, the MHC class I expression is patchy and the perifascicular areas are usually stained.

The features of PM include the presence of macrophages and activated CD8⁺ T cells in muscle fibers and the expression of MHC class I molecules on muscle fibers. Mononuclear cell invasion around non-necrotic muscle fibers in endomysial areas is a characteristic feature of IIMs. The histologic features of IBM resemble those of PM but also include unique features such as red-rimmed vacuoles and inclusions (cytoplasmic or nuclear) and amyloid deposits.¹⁵⁰ An increased number of cytochrome-c oxidase-negative fibers can also be seen, but this change is not specific for IBM. In IBM, electron microscopy usually demonstrates 15- to 21-nm cytoplasmic and intranuclear tubulofilaments, which are not found in DM or PM. It is not uncommon to find biopsies that are negative for both rimmed vacuoles and tubulofilamentous inclusions. In this situation, if the suspicion for IBM is high, it is best to obtain another sample or to treat the patient with steroids. Nonresponsiveness to treatment further supports the diagnosis of IBM in an otherwise typical patient. Inflammation surrounding necrotic fibers is a feature of some muscular dystrophies (e.g., facioscapulohumeral muscular dystrophy, limb-girdle muscular dystrophy type IIB, Duchenne's muscular dystrophy), where it is secondary to muscle cell degeneration. Thus the presence of a mononuclear infiltration surrounding

Table 85-6 Immunologic Features of Idiopathic Inflammatory Myopathies

Feature	Dermatomyositis	Polymyositis	Inclusion Body Myositis
B cell infiltration	+	−/+	−/+
T cell infiltration	+	+	+

*Inflammation is absent in a small proportion of polymyositis and dermatomyositis biopsies.

[†]Also seen in chronic neurogenic conditions and distal myopathies.

non-necrotic muscle fibers confirms the diagnosis of IBM or PM. The common and unique immunologic and histologic features of the various subgroups are listed in [Tables 85-6](#) and [85-7](#), respectively.

Molecular

One of the more tangible deliverables of the human genome product has been the development and use of microarrays for messenger RNA (mRNA) profiling. In the commonly used form of microarray, about 1 million DNA probes are placed on 1 cm² glass slides, allowing the query of each gene of the genome. Although all genes are shared among all cells, only certain genes are expressed (turned on) in any specific cell at any specific time. Messenger RNA expression profiling using microarrays allows genome-wide assessment of the response of each gene, with a comparison of normal and pathologic states.

Muscle is routinely biopsied as part of the clinical workup of muscle disease, and muscle histopathology is an important part of the diagnosis of inflammatory myopathies. Diagnostic muscle biopsies have been used for mRNA expression profiling in a series of studies, with comparisons between inflammatory myopathies (JDM, PM, IBM) and dystrophic myopathies (Duchenne's muscular dystrophy).^{169,170} These comparisons are important because they differentiate between inflammation associated with downstream myofiber degeneration or regeneration (dystrophies) and inflammatory processes that may initiate the inflammatory myopathies.

Microarrays have provided considerable new insights into DM. Early on, mRNA profiling in DM showed a predominance of type I IFN-responsive pathways, suggesting the possible persistence of an antiviral response.¹⁶⁹ Particularly prevalent was the dramatic expression of the IFN-inducible MxA gene. This signature was confirmed and extended,¹⁷¹ supporting an important role of the innate immune response, with prominent plasmacytoid dendritic cell infiltration in DM compared with the other inflammatory myopathies. The beneficial effect of intravenous

immunoglobulin (IVIG) in DM has been queried by microarrays to define the drug-responsive genes, then compared with the lack of response in IBM.¹⁷² This study suggested that IVIG suppressed a relatively small subset of inflammatory responses in DM muscle including complement (C1q) and inflammatory cell migration proteins (ICAM-1). Microarrays have helped elucidate an unexpectedly important role for innate immunity in DM. They have also provided new insights into the humoral immunity in PM and IBM. Specifically, mRNA expression profiling showed a high proportion of immunoglobulin transcripts as differentially expressed (59% of all detected genes in IBM and 33% in PM).¹⁷³ Plasma cells, defined as those terminally differentiated B cells expressing CD138 but not CD19 or CD20, were then shown to be a key differentiating cell type within IBM and PM muscle.

IMAGING

Muscles

Ultrasonography, CT, and MRI are the three general imaging techniques used to evaluate skeletal muscle. MRI has emerged as the method of choice for the examination of soft tissue muscle abnormalities because it efficiently visualizes and quantifies inflammation, fat infiltration, calcification, and alterations in muscle size and localizes pathologic changes in specific muscle groups ([Figure 85-11](#)). MRI examinations can be done on large volumes and can be helpful guides for muscle biopsy sampling. MRI is a potential outcome tool to be used in the longitudinal analysis of responses to therapy and in clinical trials, although its sensitivity to changes has not been validated.¹⁷⁴⁻¹⁷⁷

Ultrasonography is useful for detecting abnormal vascularization, and rates of blood flow can be monitored effectively with color Doppler imaging. The main disadvantage of ultrasonography is its inability to visualize deep-seated muscles in cross-section. Moreover, image analyses are more subjective than with MRI and depend to a greater degree

Figure 85-11 Magnetic resonance images (short tau inversion recovery) of the thigh. Note the symmetric inflammation in the affected muscle, seen as bright areas relative to unaffected muscle.

on the experience of the examiner.¹⁷⁸ Ultrasound muscle examinations are much more frequent in countries where physicians are responsible for performing such examinations and maintaining uniform standards for their evaluation. Ultrasonography provides a safe, noninvasive, easily portable, and relatively inexpensive approach to the evaluation of muscle abnormalities.¹⁷⁹

CT is the modality of choice for identifying calcifications in soft tissues (e.g., JDM), but it is not useful for detecting inflammatory changes in muscle tissue. Cross-sectional CT images allow quantification of muscle atrophy and fat replacement in deep muscles that may not be generally accessible to ultrasonography. A combination of MRI and P-31 magnetic resonance spectroscopy examinations produces the most comprehensive and accurate evaluation of patients.¹⁷⁴

Lungs

Radiography and high-resolution CT of the lungs are important for detecting lung involvement and should be considered at the time of myositis diagnosis because the prevalence of interstitial lung disease is high. In contrast, conventional radiography may not always be sensitive enough to detect interstitial lung disease. These are also important tests for assessing the effects of immunosuppressive treatment.

ELECTROMYOGRAPHY

Electromyogram (EMG) changes are usually nonspecific but are a useful indicator of myopathic changes. The major abnormalities include abnormal electrical irritability, decrease in the mean duration of motor unit potentials or increase in the percentage of polyphasic motor unit potentials (short duration), and rapid firing of the motor unit potentials in relation to the level of activity. Later in the course of the disease, fibers are lost from some motor units and recruitment is reduced. Abnormal electrical irritability in DM and PM involves increased insertional activity, trains of positive sharp waves, and fibrillation potentials. Spontaneous electrical activity is a reasonable measure of disease activity in DM and PM. EMG abnormalities correlate with alterations in muscle strength and serum muscle enzymes.¹⁸⁰

and are a useful measure when serum levels and muscle strength are uninterpretable. The inflammation in IIMs is often patchy, and EMG is useful in determining which muscle should be sampled for biopsy. Because EMG can cause histopathologic changes that complicate the interpretation of the biopsy, it is best to perform EMG on one side and obtain the muscle biopsy from the same muscle on the contralateral side. Even for IBM, in which the disease is often asymmetric, this technique is useful as long as the contralateral muscle is also weak.

LUNG FUNCTION TESTS

Pulmonary function tests are an important means of obtaining an objective assessment of respiratory involvement. Typically, patients demonstrate a restrictive ventilatory impairment, with decreased total lung capacity, functional residual capacity, residual volume, forced expiratory volume in 1 second (FEV₁), and forced vital capacity (FVC), but with a normal or elevated FEV₁/FVC ratio and reduced diffusing capacity for carbon monoxide. Pulmonary function tests are also important in estimating disease severity and response to therapy, in concert with radiographic examination.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of IIMs and other myopathies is important because the clinical associations and response to therapeutic interventions differ significantly. A variety of myopathies closely mimic IIMs (Table 85-8).

Dystrophic Myopathies

Dysferlinopathy

Genetic defects in the dysferlin gene result in limb-girdle muscular dystrophy type 2B and distal muscular dystrophy of the Miyoshi type. These diseases can appear in the late teens or early 20s, and the weakness in the limb-girdle type 2B phenotype first assumes a pelvifemoral distribution: the quadriceps muscle is affected first, followed by weakness in the arms in the later stages of the disease. A relatively acute

Table 85-8 Differential Diagnosis of Inflammatory Myopathies

Disease	Key Diagnostic Features	Disease	Key Diagnostic Features
Dystrophic Myopathies		Infectious Myopathies	
Dysferlinopathy (Miyoshi myopathy and LGMD2B)	Mutations in dysferlin gene Progressive proximal (LGMD2B) and distal (Miyoshi myopathy) muscle weakness Onset in late teens to early 20s Increased CK levels Inflammation in muscle biopsy Nonresponsiveness to steroids Partial deletion in D4Z4 repeats near chromosome 4q telomere at 4q35 Initial facial and shoulder girdle weakness progresses to pelvic girdle and extremities Normal serum CK levels or modest elevation	HIV myopathy	Progressive myopathy Proximal symmetric muscle weakness Endomysial inflammation Increased serum CK levels
Facioscapulohumeral muscular dystrophy	Partial deletion in D4Z4 repeats near chromosome 4q telomere at 4q35 Initial facial and shoulder girdle weakness progresses to pelvic girdle and extremities Normal serum CK levels or modest elevation	Parasitic Myopathies	
Becker's dystrophy	Mutations in dystrophin gene X-linked recessive disorders Limb-girdle weakness and cardiomyopathy High serum CK levels CCTG expansion in intron 1 of ZNF9 gene Autosomal dominant Proximal muscle weakness Mutations in sarcoglycans (α , β , γ , and δ) Limb-girdle weakness and cardiomyopathy High serum CK levels	Protozoal myopathy	Clinical features of idiopathic inflammatory myopathies Focal or diffuse inflammation Myocarditis Increased serum CK levels
Proximal myotonic myopathy		Drug-Induced Myopathies	
Sarcoglycanopathy		Zidovudine myopathy	Proximal muscle weakness Increased serum lactate levels Ragged red fibers and abnormal mitochondria in muscle Improves with drug discontinuation Necrotizing myopathy Acute or subacute painful proximal myopathy Increased serum CK levels Proximal and distal weakness Type 2 atrophy and vacuolar changes in muscle Increased serum CK levels Proximal muscle weakness and pain Inflammation and necrosis in muscle Skin changes Increased serum CK levels
Metabolic Myopathies		Statin myopathy	
Acid maltase deficiency	Mutations in acid α -glucosidase Proximal muscle weakness Respiratory muscle involvement Abnormal irritability on EMG Increased serum CK levels Mutations in myophosphorylase gene Exercise intolerance Fixed proximal muscle weakness Increased serum CK levels	Corticosteroid myopathy	
McArdle's disease		D-Penicillamine, interferon- α , and procainamide-induced myopathy	
Mitochondrial Myopathies		Neuromuscular Diseases	
	Mutations in complex I-IV, complex V, and coenzyme Q10 genes Myopathy with limb-girdle weakness Exercise intolerance and fatigue Increased serum CK levels	Motoneuron disease	Upper and lower motoneuron signs Asymmetric weakness with denervation atrophy Fasciculations and fatigability Fibrillations and enlarged motor unit potentials on EMG Modest elevation in serum CK levels Symmetric muscle weakness and atrophy Neurogenic changes on EMG and biopsy Normal serum CK levels Abnormal weakness and fatigability Decremental EMG response Antiachetylcholine receptor antibodies Positive anticholinesterase drug test
Endocrine Myopathies		Spinal muscular atrophy	
Cushing's syndrome	Insidious onset Proximal muscle weakness Normal serum CK, AST, and LDH levels Subacute onset of proximal muscle weakness Normal serum CK levels or modest elevation Respiratory muscle weakness	Myasthenia gravis	
Thyrotoxic myopathy			

AST, aspartate transaminase; CK, creatine kinase; EMG, electromyogram; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; LGMD, limb-girdle muscular dystrophy.

onset with elevated levels of serum muscle enzymes points to PM as a differential diagnosis. The weakness in the Miyoshi phenotype occurs predominantly in the gastrocnemius and soleus muscles, thereby affecting the ability to walk on the toes. The weakness is slowly progressive, with loss of ambulation generally occurring in the fourth decade, but earlier in some cases. Serum CK levels are high during the active phase of the disease. In general, the muscle biopsy

is dystrophic, with significant mononuclear cell infiltration and small sarcolemmal defects with thickened basal lamina structures over the defects.¹⁸¹

Facioscapulohumeral Muscular Dystrophy

A partial deletion of the D4Z4 repeats near the chromosome 4q telomere at 4q35 leads to the facioscapulohumeral

phenotype. The initial weakness usually affects the facial muscles, and the onset is insidious. Shoulder weakness is commonly seen because of the weakness of the scapular fixator muscles. The weakness is generally slowly progressive, with typical myopathic changes on the EMG such as brief, small-amplitude, polyphonic voluntary motor unit potentials. The presence of perivascular, endomysial, and perimysial inflammation is a common feature.¹⁸² Serum CK levels are elevated and vary with age and sex.

Dystrophinopathies

These X-linked recessive disorders are caused by mutations in the dystrophin gene. Milder forms of Becker's muscular dystrophy manifest as myalgias, muscle cramps, exercise intolerance, mild limb-girdle weakness, and quadriceps myopathy. The severe Becker's phenotype that presents before age 8 years is indistinguishable from the Duchenne's phenotype. An elevation in serum CK levels is seen in asymptomatic patients. The mean age at loss of ambulation is usually in the fourth decade. Histologic features include variation in fiber size, central nuclei, regeneration, necrosis, hypercontracted fibers, and endomysial fibrosis. In Becker's dystrophy the number of necrotic and regenerating fibers is decreased compared with the Duchenne phenotype, and the incidence of hypercontracted and central nuclei increases with age.¹⁸³ A plasma membrane defect in non-necrotic fibers and endomysial inflammation with macrophage, T cell, mast cell, and eosinophil infiltration are also characteristic features of this disease.

Proximal Myotonic Myopathy

CCTG expansion in intron 1 of the zinc finger transcription factor (ZNF9) gene results in type II myotonic dystrophy. The myotonia is usually absent or minimal but is detectable by EMG. The weakness is mainly proximal, with minimal or no facial involvement. Smooth muscle, cardiac, and diaphragmatic involvement is common in this disease. First-degree heart block is the most common abnormality, and sudden death is well documented.¹⁸⁴ Muscle biopsies show nonspecific features such as central nuclei, sarcoplasmic masses, and atrophy of type I fibers.

Sarcoglycanopathy

Mutations in sarcoglycans (α , β , γ , and δ) result in limb-girdle muscular dystrophy types IIC to IIF. Sarcoglycanopathies often start in childhood, with a median age of onset of 6 to 8 years. These diseases present initially as pelvic muscle weakness including a waddling gait and difficulty performing common tasks such as getting up from the floor, climbing the stairs, and running. The trunk muscles are prominently affected, and upper extremity involvement usually follows lower extremity involvement. Distal muscles are generally spared until later in the disease process.¹⁸⁵ These progressive disorders result in high levels of serum CK early in the disease; the levels decrease when patients become wheelchair bound by 12 to 16 years of age. Dilated cardiomyopathy is often seen in these disorders, and muscle biopsies show marked regeneration and necrosis.

Neuromuscular Disorders

Motoneuron Diseases

These diseases including amyotrophic lateral sclerosis (ALS) are progressive, degenerative disorders of motoneurons in the spinal cord, brain stem, and cerebral motor cortex that manifest clinically as amyotrophy and exaggerated reflexes. These diseases are characterized by a selective loss of function of upper or lower motoneurons, finally leading to a progressive loss of both types of motoneurons over time. EMG shows fibrillation and fasciculation potentials in the muscles of the lower and upper limbs or in the bulbar muscles. Muscle biopsies show the presence of denervation atrophy and secondary myopathic changes in chronically denervated muscles. IBM is the primary muscle disorder most likely to be confused with ALS, and muscle biopsy helps differentiate the two. Serum CK levels are slightly elevated, particularly in the early stages of the disease and in men who are physically active.

Spinal Muscular Atrophy

Late-onset forms of spinal muscular atrophy (SMA) are characterized by progressive muscle weakness and atrophy and reduced tendon reflexes. EMG and muscle testing reveal neurogenic changes in the muscle. Typical muscle biopsy findings include small and large groups of atrophic fibers in the chronic and severe forms of SMA, respectively. Histochemical changes show fiber type grouping, indicating reinnervation. Serum CK levels are slightly increased in juvenile-onset cases and normal in other forms of SMA. EMG shows abnormal spontaneous electrical activity (fibrillations, positive sharp waves, fasciculations), suggesting ongoing denervation.

Myasthenia Gravis

The clinical manifestations of myasthenia gravis include abnormal weakness that is worsened by repeated or sustained exertion and fatigability. Proximal muscles are usually more severely affected than distal muscles. This is a generalized disease that exhibits external ocular muscle involvement, positive anticholinesterase drug tests, and a decremental EMG response. Patients are often positive for antiacetylcholine receptor antibodies.

Metabolic Myopathies

Acid Maltase Deficiency

This autosomal recessive glycogen storage disease is caused by acid maltase gene mutations. The disease has infantile, childhood, and adult variants. The infantile form manifests in the first few months after birth as rapidly progressive weakness and hypotonia, with death occurring as a result of cardiorespiratory failure. The childhood form manifests as a myopathy in which the weakness is usually greater in the proximal than in the distal muscles; the disease progresses relatively slowly, and patients die of respiratory failure. The adult form presents in the 20s as a progressive myopathy that resembles PM or limb-girdle muscular dystrophy, with

additional respiratory symptoms. Serum muscle enzymes (CK, AST, and LDH) are increased in all three forms of the disease, and EMG indicates myopathy in all three cases. Histologic examination reveals a vacuolar myopathy, with the vacuoles displaying a high glycogen content and strongly positive staining for acid phosphatase; necrotic and regenerating fibers are uncommon.

McArdle's Disease

McArdle's disease is the most common of the nonlysosomal muscle glycogenoses. Exercise intolerance is the characteristic feature of this disease, and it often manifests as early fatigue, myalgia, and stiffness of exercising muscle that is relieved by resting. The EMG is normal in some patients; it shows nonspecific myopathic changes in others. Forearm ischemic exercise testing shows virtually no increase in venous lactate in most patients. Serum CK levels, however, are variably elevated in these patients. Muscle biopsies show subsarcolemmal deposits of glycogen at the periphery of the fibers.

Mitochondrial Myopathies

Mitochondrial diseases are heterogeneous and often present a diagnostic challenge. It has been suggested that myopathy is due to mutations in mitochondrial DNA in the skeletal muscle.¹⁸⁶ The clinical course of the pure myopathy varies from rapidly progressive to almost reversible disease, with disease onset occurring from infancy through adulthood. The weakness is facioscapulohumeral and more proximal than distal, with involvement of the orbicularis and extraocular muscles. Patients often complain of exercise intolerance and fatigue and have recurrent episodes of myoglobinuria. Muscle biopsy plays a critical role in the diagnosis of these conditions, especially the use of special histochemical stains that detect succinate dehydrogenase, Cox staining, and Gomori trichrome staining.

Endocrine Myopathies

Cushing's Syndrome

Cushing's syndrome is an endogenous glucocorticoid excess disease that manifests as muscle weakness and wasting. Chronic corticosteroid treatment results in similar manifestations and significant loss of strength within a few weeks of treatment. Muscle biopsy shows increased vacuolations and glycogen accumulation in type II muscle. The onset of weakness is usually insidious. The weakness is primarily proximal, with more severe involvement in the legs than in the arms. These patients generally show normal serum muscle enzyme levels (CK, AST, and LDH). Muscle wasting can often be reversed if the glucocorticoid levels are returned to the normal range.

Hyperthyroid and Hypothyroid Myopathy

Myopathic thyroid disease is characterized primarily by proximal muscle weakness and muscle wasting. When distal weakness occurs, it often follows proximal myopathy. Exercise intolerance, fatigue, and breathlessness are

common complaints, and weakness of the respiratory muscles results in respiratory insufficiency and the need for ventilatory support. Patients often have difficulty rising from a sitting position or lifting their arms above their heads. Serum muscle enzymes (CK, AST, and ALT) are often normal or low in hyperthyroidism and elevated in hypothyroidism. EMG findings are variable, with short-duration motor unit potentials and increased polyphasic potentials in proximal muscles; fibrillations and fasciculations are uncommon. Muscle biopsy shows atrophy in fiber types, nerve terminal damage, fatty infiltration, and isolated fiber necrosis, with macrophage and lymphocyte infiltration.

Infectious Myopathies

Human Immunodeficiency Virus Myopathy

Neuromuscular manifestations are common in human immunodeficiency virus (HIV)-induced myopathy. The clinical features typically include a myopathy of subacute onset that progresses slowly. The myopathy often starts as proximal symmetric muscle weakness with or without muscle wasting, similar to that in IIMs. Histologic features include muscle fiber necrosis, inflammation, and vacuolated muscle fibers, with a significant increase in serum CK levels. EMG shows spontaneous activity, with fibrillation potentials, positive sharp waves, and brief, low-amplitude polyphasic motor unit potentials.

HTLV-1 Myopathy

Myositis associated with human T-lymphotropic virus I (HTLV-I) has been noted in certain areas of the world (e.g., Japan, Jamaica). In these patients, symptoms of PM and IBM occur either alone or in combination with tropical spastic paraparesis.¹⁸⁷ Typical features include weakness and increases in serum CK levels. Histologic findings include interstitial inflammation, muscle fiber necrosis in PM and endomysial inflammation, vacuoles, amyloid deposits, and tubulofilaments in IBM.

Parasitic Myopathies

Diseases caused by various parasites—protozoa (e.g., toxoplasmosis, trypanosomiasis, sarcocystosis, malaria), cestodes (e.g., cysticercosis, echinococcosis, coenurosis, sparganosis), and nematodes (trichinellosis, taxocariasis, racunculiasis)—can cause myositis. The clinical features include nonspecific complaints such as myalgia and focal swelling, as well as typical features of PM and DM. Each parasitic infection shows typical changes on muscle biopsy (e.g., the presence of tachyzoites and toxoplasma cysts along with perimysial and endomysial inflammation). A combination of muscle biopsy and serologic findings is useful in making a diagnosis.

Drug-Induced Myopathies

Drugs can induce myopathic changes either by acting directly on the muscle or by indirectly influencing various factors required for muscle cell survival and growth.

Zidovudine Myopathy

Nucleoside analogues such as zidovudine are used to treat HIV because they act as false substrates for the viral reverse transcriptase. These drugs also cause myalgias, proximal muscle weakness, and fatigue and are sometimes associated with increased levels of serum CK. EMG shows typical myopathic changes. Histologically, muscle fibers show ragged red fibers; atrophic fibers show marked sarcoplasmic changes, with rod-body formation. Pronounced abnormalities in mitochondria, myofilaments, and tubules are also noted by electron microscopy. It has been suggested that these drugs also inhibit mitochondrial DNA polymerase, thus producing the mitochondrial abnormalities. Discontinuation of therapy improves muscle strength and function. In these patients, zidovudine-induced mitochondrial myopathy may coexist along with HIV-induced T cell-mediated inflammatory myopathy.¹⁸⁸

Statin Myopathy

Statins are lipid-lowering drugs (e.g., lovastatin, simvastatin) that are known to cause necrotizing myopathy. These HMG-CoA reductase inhibitors generally suppress specific cholesterol synthesis and lower plasma concentrations of low-density lipoprotein. The clinical features of this condition include myalgia, cramps, and acute and subacute painful proximal myopathy, with histologic features varying from mild, discrete, and unspecific to muscle fiber necrosis, mononuclear cell infiltration, and myophagocytosis and regeneration. A mild increase in serum CK levels is also noted. Other agents that are known to cause necrotizing myopathy include fibric acid derivatives (clofibrate, gemfibrozil); nicotinic acid; organophosphate poisoning; and ϵ -aminocaproic acid.

Other Drugs

D-penicillamine is known to induce clinical features reminiscent of DM; recovery usually occurs after withdrawal of the drug. Agents such as IFN- α that are used to treat viral hepatitis and certain malignant tumors are also known to induce clinical features that resemble PM. Amphiphilic drugs such as chloroquine, hydroxychloroquine, and amiodarone are also known to induce cytoplasmic vacuoles, necrosis, and longitudinal branching of muscle fibers.¹⁸⁹ Drugs that affect microtubules such as colchicines and vincristine also induce myopathic changes, with the appearance of characteristic autophagic vacuoles in muscle fibers.

MANAGEMENT AND OUTCOME

The recommended treatment for patients with PM or DM is based on a combination of pharmacologic therapy and physical exercise. The optimal pharmacologic treatment in PM and DM is unclear. Few controlled trials have been undertaken, so recommendations are based on clinical observations from case series. With these limitations in mind, a suggested outline of treatment for patients with PM or DM is depicted in [Figure 85-12](#). In addition

to providing treatment, it is important to give patients adequate information about their disease and its treatment. This educational component is best provided by a rheumatology team and patient support groups.

Pharmacologic Treatment

The initial pharmacologic treatment in PM and DM is high-dose glucocorticoids: 0.75 to 1 (up to 2) mg/kg body weight per day for 4 to 12 weeks. Most experts recommend that glucocorticoid treatment be combined with another immunosuppressive drug to reduce the side effects of the glucocorticoids and to boost the immunosuppressive effect. The most frequently used immunosuppressive agents are azathioprine and methotrexate. In the extension phase of one of the few double-blind, placebo-controlled trials that have been reported, the combination of azathioprine and glucocorticoids, as compared with prednisone alone, was associated with better functional ability and a lower requirement for prednisone after 1 and 3 years.^{190,191} The recommended azathioprine dosage is 2 mg/kg per day. The dosing regimen for methotrexate is similar to that for rheumatoid arthritis—up to 25 mg weekly, although there have been reports of higher doses. Pulmonary involvement related to myositis does not seem to be a contraindication for methotrexate.

The combination of methotrexate and azathioprine proved to be successful in a few patients with refractory myositis in a prospective, randomized, open-label crossover study comparing two aggressive approaches. There are also newer reports that mycophenolate mofetil might be effective. In patients with interstitial lung disease, cyclophosphamide could be of value. There are also a few reports that cyclosporine A or tacrolimus can be beneficial in these cases.^{192,193} In treatment-resistant DM, a high dose of IVIG was found to have a beneficial effect on muscle strength when compared with placebo; however, the therapeutic effect was temporary, and repeated infusions were required.¹⁹⁴ In patients with severe, rapidly progressive disease that might be life threatening, high-dose pulses of intravenous methylprednisolone have been reported to be beneficial. Pharmacologic treatment including tapering of the corticosteroid dose should be guided by clinical outcome measures. As discussed earlier, the most appropriate outcome measures are muscle endurance and muscle strength. Side effects of glucocorticoids in these high doses are frequent. Prophylaxis against osteoporosis is recommended with vitamin D and calcium and, when clinically indicated, bisphosphonates. Steroid myopathy is another possible consequence of glucocorticoid treatment that is particularly problematic in patients with inflammatory myopathies. There is no specific test to verify steroid myopathy, but in the absence of active clinical disease, steroid myopathy could contribute to muscle weakness. If steroid myopathy is suspected, tapering of the glucocorticoid dose with careful evaluation of the clinical response is recommended. Glucocorticoids may also cause hypokalemia, and if this is not corrected, it may be associated with muscle weakness and incorrectly interpreted as myositis activity.

The depletion of B cells has recently emerged as a new strategy in autoimmune diseases. One approach is to use rituximab (monoclonal antibody against CD20). There are

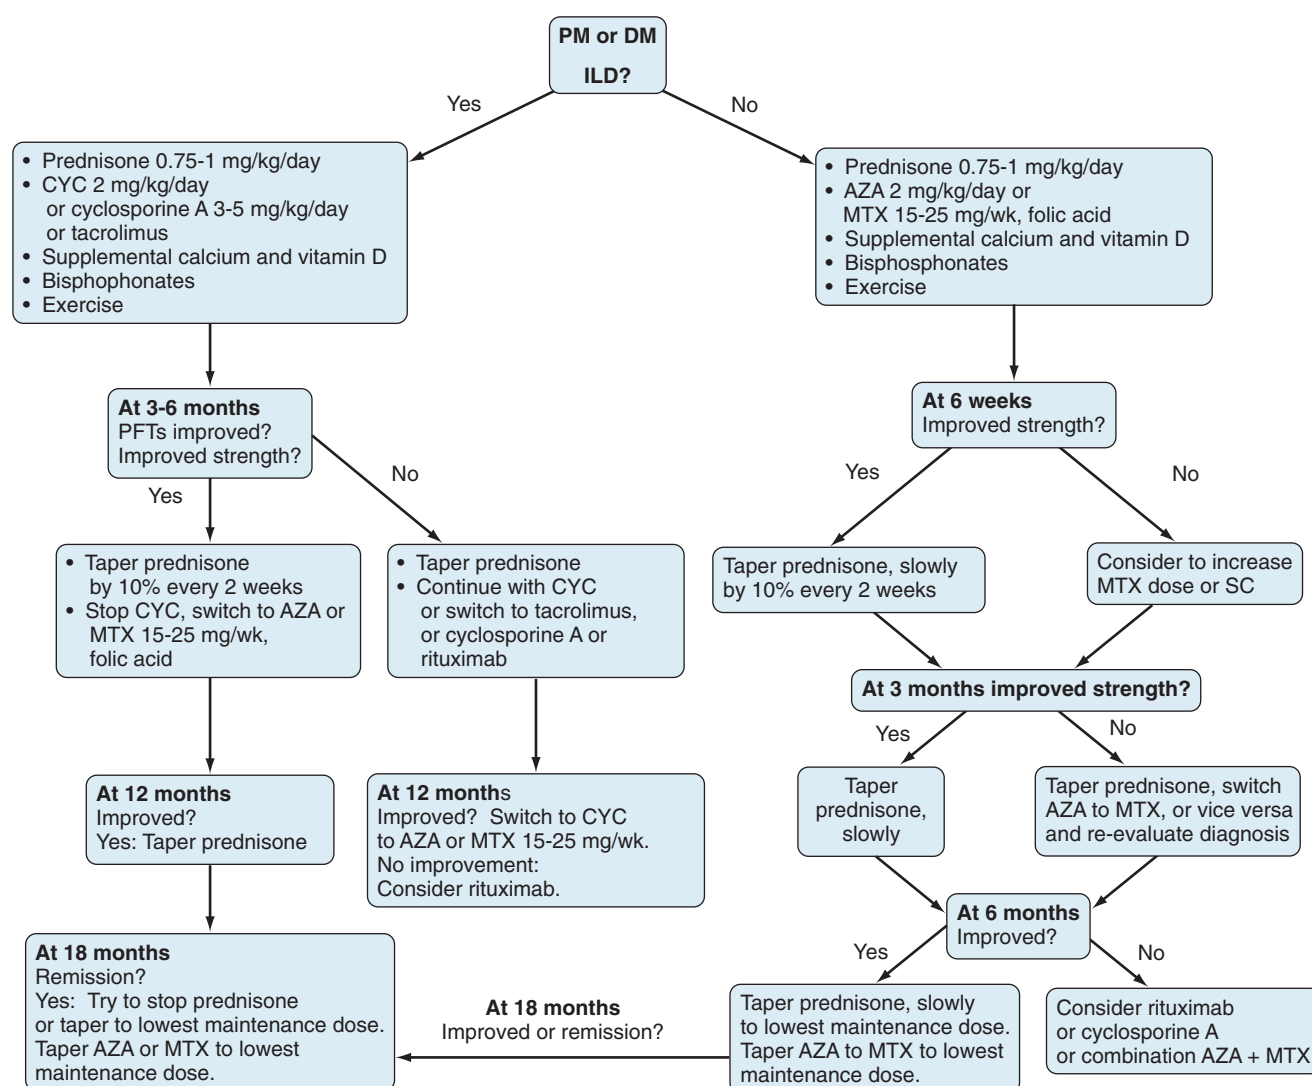

Figure 85-12 Treatment algorithm for adult patients with polymyositis (PM) or dermatomyositis (DM). AZA, azathioprine; CYC, cyclophosphamide; ILD, interstitial lung disease; MTX, methotrexate; PFT, pulmonary function test; SC, subcutaneous.

a few case series suggesting a beneficial effect of depleting B cells in patients with DM or PM.¹⁹⁵⁻¹⁹⁷ A large international multicenter trial of B cell depletion is currently under way. Use of anti-TNF treatments produced mixed results. For example, treatment with infliximab at 3 mg/kg resulted in improved muscle function in patients with juvenile DM. However, interpretation of the data from this trial was complicated by the fact that all patients were concomitantly being treated with a tapering dose of prednisone during the trial.¹⁹⁸ A second, larger trial examining the use of infliximab in patients with PM, DM, or IBM found that only 30% of patients experienced an improvement in disease symptoms, while the remaining participants suffered from adverse side effects or worsening of the disease.¹⁹⁹

IBM is usually nonresponsive to glucocorticoids. There are occasional case reports of “stabilization” for a period of months, but this condition probably reflects the natural history of the disease. Prolonged administration of glucocorticoids to IBM patients may actually lead to worsening of clinical aspects of the disease, despite the improvement in

CK levels and reduced T cell numbers in biopsies. Prednisone treatment also increases the number of amyloid-containing fibers.

A few small studies have shown some beneficial effect of methotrexate, anti-T lymphocyte globulin, or mycophenolate. Anabolic steroids and oxandrolone may have some beneficial effects on muscle strength, although this benefit needs to be confirmed in larger studies. Most experts consider their use justified in combination with glucocorticoids for a limited period in patients who have inflammatory infiltrates on muscle biopsy, or in combination with a more aggressive immunosuppressive treatment (e.g., methotrexate, azathioprine) in patients with another connective tissue disease.

Nonpharmacologic Treatment

With immunosuppressive treatment, approximately 75% of patients improve, but few recover normal muscle function, even in the absence of muscle inflammation. In previous

decades, patients with myositis were cautioned against exercise due to concerns over possible muscle damage and inflammation, but recent publications have demonstrated that combining exercise and immunosuppressive therapy is a safe approach and has clear beneficial effects on muscle function.²⁰⁰ In a pair of small studies of immunosuppressed myositis patients, it was demonstrated that personalized sub-maximal exercise programs improved muscle function without causing any increase in inflammation. This was true for patients who had individually tailored exercise regimens²⁰¹ and self-administered home exercise routines.²⁰² Examinations of patient biopsies both before and after exercise indicated that the patients showed improved muscle strength due to an increase in the proportion of slow twitch (type I) muscle fibers and reduction of inflammation and fibrosis.^{202,203} Combining exercise and immunosuppressive therapy is a safe approach and has clear beneficial effects on muscle function.¹⁹⁸ The exercise regimen should be individualized and supervised by a physiotherapist to avoid the overuse of muscles. Physical exercise is now recommended as combination therapy with immunosuppressive treatment.

Assessing Disease Activity and Outcome

The most important variable to measure in myositis patients is muscle performance or physical function. However, it is equally important to evaluate whether impaired muscle function reflects disease activity or irreversible muscle damage.

Muscle Examination

Manual Muscle Test. There are several tools to measure muscle performance, but the most often used method in clinical practice and clinical trials is the manual muscle test with the MRC scale (see earlier). The drawback is that these tools measure muscle strength but not muscle endurance, which is often a major problem in PM or DM. Further, they have not been validated in adults with inflammatory myopathies. Previously, the number of muscle groups tested using the manual muscle test varied and different scales were used (5 or 10 grade). Recently, a consensus was reached to assess eight muscle groups on the dominant side using a 0- to 10-point scale, where 0 is no muscle contraction, 5 is ability to hold the test position without any added pressure, and 10 is ability to hold the test position against strong pressure. The points between these scores are based on gradual increased resistance against the examiner's pressure. The eight muscle groups tested are neck flexors, shoulder abduction (deltoid middle), biceps brachii, wrist extensors, knee extensors (quadriceps), dorsiflexion of ankle, gluteus maximus, and gluteus medius. The score achieved varies between 0 and 80.

Functional Index in Myositis. The Functional Index in Myositis and its revised form, the Functional Index in Myositis-2, were developed as outcome measures for patients with PM or DM. This test measures the number of repetitions that can be performed in defined muscle groups.^{157,162} It is a more sensitive method of measuring impaired muscle function in patients with PM or DM.¹⁵⁷ The drawback is

that it takes a longer time to perform than the manual muscle test, and it may be difficult to use in everyday clinical practice. Preferably, the Functional Index in Myositis-2 is administered by a physiotherapist and can be combined with the manual muscle test.

Extramuscular Involvement

In some patients, extramuscular symptoms predominate among the clinical features. These symptoms may require other assessment tools such as those used to evaluate interstitial lung disease. For monitoring the effects of treatment of interstitial lung disease, high-resolution CT and pulmonary function tests are recommended.

Disease Activity and Damage

It is also important to distinguish whether symptoms are caused by active inflammatory disease or are a consequence of organ damage. IMACS, an international collaboration, made a consensus recommendation that outcome measures for patients with myositis include tools that measure disease activity, damage, and quality of life. The IMACS network developed one outcome measure to assess myositis disease activity and one to measure organ damage: the myositis disease activity assessment tool and the myositis damage index, respectively.¹⁵⁶ The disease activity outcome measure is a core set that consists of the six variables listed in Table 85-9. The damage index is recorded by the physician on the basis of the patient's history and covers several organ systems that can be affected in patients with inflammatory myopathies. To assess the impact on general health, the generic Short Form 36, a self-administered health-related quality of life questionnaire, is recommended. These outcome measures have been developed for clinical trials and research but can also be useful in clinical practice. More detailed information about these outcome measures can be found on the IMACS website: <https://dir-apps.niehs.nih.gov/imacs>.

IMACS has also reached a consensus on what constitutes improvement. Improvement is based on the disease activity core set and is defined as greater than 20% improvement in three of the six variables of the core set, with two or fewer of the variables (except the manual muscle test) worsening by less than 25%. However, this definition of improvement must be validated in longitudinal studies.

Table 85-9 Disease Activity Measure: Core Set

Physician's overall assessment of disease activity on a visual analogue scale (VAS)
Patient's or parent's overall assessment of disease activity (VAS)
Functional assessment (health assessment questionnaire)
Muscle strength testing (manual muscle test)
Serum levels of at least 2 of 4 muscle enzymes (CK, LDH, AST, ALT)
Extramuscular score (myositis disease activity assessment VAS [MYOACT] or myositis intention to treat activity index [MITAX]), in which disease activity in 7 organ systems (general symptoms, skin, joints, gastrointestinal tract, pulmonary, heart, and muscles) is scored

ALT, alanine transaminase; AST, aspartate transaminase; CK, creatine kinase; LDH, lactate dehydrogenase.

KEY POINTS

Diffuse connective tissue diseases are usually associated with autoimmunity to spliceosomal components (U-RNPs, heterogeneous RNPs), nucleosomal components (nucleosomes, DNA, histones), and proteosomal components (HC9, LMP2).

Apoptotic modification of molecules often renders them more antigenic.

The evolution of symptoms may be associated with molecular mimicry and epitope spreading.

In their early stages many autoimmune connective tissue diseases are not clinically well differentiated; this stage of disease progression is called *undifferentiated connective tissue disease* (UCTD).

About 50% of UCTDs remain undifferentiated.

Important clues about the eventual direction of differentiation can be obtained from nail-fold capillary microscopy and the type of autoantibody profile combined with regular clinical evaluations.

Mixed connective tissue disease (MCTD) is the prototypical overlap disease with features of lupus, scleroderma, and inflammatory myositis. This overlap is not seen at the outset of MCTD; rather it often takes several years to develop.

The most common presentation of MCTD is Raynaud's phenomenon.

MCTD is most commonly associated with antibodies to U1-RNP; in general this antibody predicts lack of severe renal and central nervous system involvement.

The major cause of death in MCTD is pulmonary hypertension, and all MCTD patients should have regular echocardiograms to determine its evolution.

The management of overlap syndromes is based on the usual treatment of the constituent features of its clinical components (i.e., systemic lupus erythematosus, scleroderma, and inflammatory muscle disease).

The clustering of symptoms and signs into readily recognizable groupings has an important historic precedence in the classification of disease. With the progress of knowledge, such groupings may become more precisely defined in terms of distinctive pathology, specific laboratory findings, and genetic associations. According to current nosology, there are six autoimmune connective tissue diseases (AICTDs):

1. Systemic lupus erythematosus (SLE)
2. Scleroderma (Scl)
3. Polymyositis (PM)

Overlap Syndromes

ROBERT BENNETT

4. Dermatomyositis (DM)
5. Rheumatoid arthritis (RA)
6. Sjögren's syndrome

All six classic AICTDs are descriptive syndromes without a "gold standard" for diagnosis. The diagnosis of a well-differentiated AICTD is usually readily apparent without recourse to extensive investigations. However, in the early stages, there are often common features such as Raynaud's phenomenon, arthralgias, myalgias, esophageal dysfunction, and positive tests for antinuclear antibodies (ANA). In such cases the diagnosis is not always so obvious; this is often referred to as undifferentiated connective tissue disease (UCTD).¹ About 35% of such patients have clinical overlap syndromes, whereas most differentiate into a clinical picture consistent with the traditional description of an AICTD. In some instances one AICTD evolves into another AICTD over time.

The propensity for differentiation into a classic AICTD or the maintenance of an overlap state is often associated with distinctive serologic profiles and major histocompatibility (MHC) linkages. Although most rheumatologists generally feel more comfortable thinking in terms of the classic AICTD paradigms, a case can be advanced for using serologic profiles and human leukocyte antigen (HLA) typing to better understand the clinical features and prognoses. In this respect a careful analysis of the overlap syndromes and their serologic associations has provided insights for understanding the clinical heterogeneity of the AICTDs.² Researchers have reported numerous clinical correlations of autoantibodies (Table 86-1).

EPIDEMIOLOGY

The reported prevalence of AICTDs is variable, depending on methodology, nature of referral bias, and ethnicity.³ It is generally accepted that Sjögren's syndrome has the highest prevalence (0.5 to 3.6%), with SLE being much lower at about 15 to 50 per 100,000. Scleroderma, polymyositis, and dermatomyositis are relatively rare AICTDs, occurring in fewer than 10 per 100,000. Experts are increasingly realizing that overlap syndromes of scleroderma and myositis are more common than the "pure" forms of the disease.⁴ There are no epidemiology studies of overlap syndromes, apart from Japan, where the reported prevalence of mixed connective tissue disease (MCTD) was 2.7 per 100,000. The syndrome of MCTD usually occurs as an isolated finding, but there are reports of a familial occurrence. Unlike SLE, precipitation by sun exposure has not been described in patients with MCTD. Likewise, drug exposure has not been related to the onset of MCTD, although a transient appearance of anti-RNP antibodies has been seen at the initiation

Table 86-1 Correlations of Autoantibodies with Clinical Features

Autoantigen	Clinical Associations
Rheumatoid factor	RA, erosive arthritis, cryoglobulinemia
Anticyclic citrullinated protein	RA
Nucleosome	SLE, Scl, MCTD
Proteasome	SLE, PM/DM, Sjögren's syndrome, multiple sclerosis
Sm snRNP	SLE
Histones H1, H2A, H2B, H3, H4	SLE, UCTD, RA, PBC, generalized morphea
Ribosomal P	SLE psychosis
dsDNA	SLE, glomerulonephritis, vasculitis
ACL/ β_2 -glycoprotein	SLE, thrombosis, thrombocytopenia, miscarriages
β_2 -glycoprotein-independent ACL	MCTD (not associated with APL syndrome)
68-kD peptide of U1-RNP	MCTD, Raynaud's, pulmonary hypertension
U1 snRNP	MCTD, SLE, PM
hnRNP-A2 (also called RA-33)	MCTD, RA, erosive arthritis in SLE and Scl
Ro/La	Sjögren's, SLE, congenital heart block, photosensitivity, PBC
Fodrin	Sjögren's, glaucoma, moyamoya disease
Platelet-derived growth factor	Diffuse and limited Scl
Topoisomerase I (Scl-70)	Diffuse Scl with prominent organ involvement
Centromere	Limited Scl, CREST, Raynaud's, pulmonary hypertension, PBC
Th/To	Limited Scl
U3-snRNP	Limited Scl
hnRNP-I	Scl (early diffuse and limited)
RNA polymerases I and III	Scl (diffuse with renovascular hypertension)
Fibrillarin	Severe generalized Scl
Ku	Myositis overlap, primary pulmonary hypertension, Graves' disease
U5-snRNP	Myositis overlap
PM/Scl	Myositis overlap with arthritis, skin lesions, mechanic's hands
Signal recognition particle	Myositis overlap (severe course with cardiac disease)
Antisynthetases (Jo-1, PL-7, PL-12)	Myositis overlap with arthritis and interstitial lung disease
Mi-2	Dermatomyositis
Proteinase-3	Granulomatosis with polyangiitis (formerly Wegener's granulomatosis), pulmonary capillaritis
Myeloperoxidase	Churg-Straus, pauci-immune glomerulonephritis
Endothelial cell	Pulmonary hypertension, severe digital gangrene
α -Enolase	Behçet's, RA, MCTD, Scl, Takayasu's
Angiotensin-converting enzyme 2	AICTDs with vasculopathy

ACL, anticardiolipin; AICTDs, autoimmune connective tissue diseases; APL, antiphospholipid syndrome; CREST, syndrome of calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia; DM, dermatomyositis; hn, heterogeneous nuclear; MCTD, mixed connective tissue disease; PBC, primary biliary cirrhosis; PM, polymyositis; RA, rheumatoid arthritis; RNP, ribonucleoprotein particle; Scl, scleroderma; SLE, systemic lupus erythematosus; sn, small nuclear; UCTD, undifferentiated connective tissue disease.

of procainamide therapy.⁵ Vinyl chloride and silica are the only environmental agents that have been associated with MCTD so far.

AUTOIMMUNITY IN OVERLAP SYNDROMES

Compelling evidence indicates that autoimmunity is often antigen driven by components of subcellular particles, in particular spliceosomes, nucleosomes, and proteasomes.⁶

Autoimmunity to Spliceosomal Components

Certain components of the spliceosome are common targets of autoimmunity in the AICTDs.⁷ Furthermore, it appears that post-translational modifications of these molecules, as occurs during apoptosis, are often associated with increased immunogenicity.⁸ Spliceosomes are complex nuclear particles made up of some 300 distinct proteins and 5 RNAs, which are involved in the processing of premessenger RNA (pre-mRNA) into mature "spliced RNA."⁹ Two major spliceosomal subunits are antigenic targets in autoimmunity: (1) small nuclear ribonucleoprotein protein particles (snRNPs) and (2) heterogeneous nuclear RNP particles (hnRNPs).

The snRNPs contain small RNA species ranging in size from 80 to 350 nucleotides that are complexed with proteins.⁶ These RNAs contain a high content of uridine and are therefore called U-RNAs; 5 different U-RNAs were defined on the basis of immunoprecipitation (U1, U2, U4, U5, and U6). Autoantibodies to these complexes are mainly directed to the protein components. Anti-Sm antibodies precipitate five proteins with molecular weights of 28,000 (B'B), 16,000 (D), 13,000 (E), 12,000 (F), and 11,000 (G); five of these polypeptides are common to the U1, U2, U4, U5, and U6 RNAs. Anti-RNP antibodies precipitate three proteins with molecular weights of 68,000 (70K), 33,000 (A'), and 22,000 (C); these polypeptides are uniquely associated with U1 RNA (Figure 86-1). The clinical correlates considered to be distinctive of MCTD are associated with the 70-kD specificity with an immunodominant epitope embracing amino acid residue 125 flanked by important conformational residues at positions 119-126 (see Figure 86-1). On the other hand, SLE is associated with anti-Sm antibodies.

The hnRNPs are among the most abundant proteins in the eukaryotic cell nucleus. They contain pre-mRNA associated with 30 small proteins that are all structurally related and have molecular weights of 33 to 43 kD. Nine hnRNP core proteins have been designated A1, A2, B1a, B1b, B1c, B2, C1, C2, and C3. An antibody termed anti-RA33, which

Figure 86-1 The spliceosome is made up of five small nuclear RNAs (snRNAs) complexed with proteins to form a small nuclear ribonucleoprotein particle (snRNP). This subcellular structure is responsible for splicing introns from pre-mRNA to form mRNA via a 59-splice recognition site. Antibodies to various spliceosomal constituents are a common feature of autoimmune rheumatic disorders with a tendency to associate with different clinical profiles (see [Table 86-1](#)). The U1 small nuclear RNP (U1-snRNP) particle of the spliceosome is composed of U1-RNA, RNP proteins (70 kD, A, and C), and common Sm proteins (B', D, E, F, and G). The structure of U1-RNA consists of single-stranded RNA and double-stranded RNA called stem loops (SL) 1, 2, 3, and 4. An electron density map of the functional core of U1-snRNP at 5.5 Å resolution has enabled the spatial visualization of the RNA and placement of the seven Sm proteins, U1-C, and U1-70K into the map. A striking feature is the amino (N)-terminal polypeptide of U1-70K, which extends over a distance of 180 Å from its RNA binding domain, wraps around the core domain consisting of the seven Sm proteins, and finally contacts U1-C, which is crucial for 59-splice-site recognition. (Modified from Newman J: *Structural studies of the spliceosome*, Curr Opin Struct Biol 20:82–89, 2010; and Pomeranz AD: *Crystal structure of human spliceosomal U1 snRNP at 5.5 Å resolution*, Nature 458:457–480, 2009.)

targets the 33-kD hnRNP-A2, is particularly interesting because it is found in about one-third of sera from patient with RA, SLE, and MCTD.¹⁰ It also has associations with patient subsets of erosive arthritis in SLE, scleroderma, and MCTD and predicts the eventual development of RA in patients with early polyarthritis.¹¹ Importantly, this association with anti-RA33 is not seen in scleroderma (sine erosions), PM, or overlaps of PM/Scl or PM/DM. The antigenic epitopes of hnRNP-A2 contain two RNA binding regions at the N-terminal end and a glycine-rich C-terminal region. Certain disease subsets target these two RNA binding regions differently. For instance, RA and SLE sera preferentially react with the complete second RNA binding domain, whereas MCTD sera target an epitope that spans both RNA binding domains.

Autoimmunity to Nucleosomal Components

Nucleosomes are the compact building blocks of chromatin and consist of an octamer of two copies of histones H2A, H2B, H3, and H4, wrapped around approximately 146 base pairs of DNA ([Figure 86-2](#)). During apoptosis endonucleases cleave chromatin with the liberation of nucleosomal particles. Following the release into the cytoplasm, nucleosomes migrate to the surface of the dying cell¹² and thus become accessible to B cell receptors. The development of autoimmunity has been linked to defective phagocytosis of

apoptotically released constituents.¹² Nucleosomal antibodies are directed to antigenic determinants on the intact nucleosome rather than its individual components, DNA and histones. In a study of 496 patients with 13 different AICTDs and 100 patients with hepatitis C, antinucleosome antibodies were found in the sera of patients with SLE (71.7%), Scl (45.9%), and MCTD (45.0%).¹³

Autoimmunity to Proteasomal Components

The 26S proteasome is a large subcellular particle involved in the degradation of proteins that have been tagged with ubiquitin, resulting in the generation of peptides for presentation by the MHC class I molecules ([Figure 86-3](#)). There is good evidence that it is the target of an autoimmune response in AICTD. Antibodies to proteasomal subunits have been reported in patients with autoimmune myositis, systemic lupus erythematosus, and primary Sjögren's syndrome. Circulating 20S proteasomes (c20S) subunits appear to have an association with disease activity in MCTD and SLE.¹⁴

Generation of Autoimmunity

The antibody response to just one component of an intracellular structure such as a spliceosome will result in the uptake of the entire particle by antigen-presenting cells

Figure 86-2 The nucleosome is the fundamental repeating unit of chromatin. The central part of the nucleosome is composed of a tetramer composed of two molecules of histones H3 and H4, flanked by two dimers of histones H2A and H2B. This central core is surrounded by two super-helical turns, consisting of 146 base pairs of histone-free DNA. Histone H1 is located at the point where DNA enters and exits the nucleosome. Antibodies to the nucleosome arise early in the evolution of systemic lupus erythematosus—before anti-DNA and antihistone antibodies. Thus the nucleosome is thought to be an important early autoantigen in the development of epitope spreading. Nucleosome antibodies are also found in scleroderma and mixed connective tissue disease. (From Amoura Z, Koutouzov S, Piette C, et al: *The role of nucleosomes in lupus*, *Curr Opin Rheumatol* 12:369–373, 2000.)

(APCs). Thus all the proteins making up the particle will be subject to antigen processing with potential peptide presentation linked to their affinity to class II HLA antigens. Depending on the polymorphisms of the individual HLA molecules, there will be a diversification of the antibody response to include some of these other antigens. This process is called *epitope spreading* and is considered pivotal in the development of the linked antibody responses that are observed in different connective tissue diseases (CTDs).¹⁵ For instance, it has been shown that the induction of an immune response to one component of a U-RNP complex can induce a diversified autoantibody response to other components of the complex.¹⁶ In this way an immune response becomes modified over time, and this change has been associated with changes in the clinical picture.

The interaction between T cell receptors and peptides presented by HLA molecules is a critical event in the generation of autoimmunity. The 70-kD and anti-U1-RNP antibody responses are associated with the HLA DR4 and DR2 phenotype.¹⁷ In a transgenic murine model of MCTD, the majority of T cells targeted a limited number of epitopes residing within the RNA binding domain of the 70-kD antigen.¹⁸ DNA sequencing of HLA-DB genes has revealed that DR2- and DR4-positive patients share a common set of amino acids in the beta chain at positions 26, 28, 30, 31, 32, 70, and 73 that form a pocket for antigen binding. It is hypothesized that these two HLA subtypes represent a critical genetic specificity for the presentation of antigenic peptides to their cognate T cell receptors. The shared epitope on HLA-DR4/DR2 that is associated with an anti-U1-RNP response is different from the shared epitope associated with HLA-DR4/DR1 in RA patients.¹⁹ The 70-kD polypeptide has several different epitopes, the most consistent sequence being KDK DRD RKR RSS RSR.²⁰ This region is preferentially targeted by MCTD sera but not by SLE sera.²¹ The autoimmune response to the spliceosome in these three

disorders is characterized by differential degrees of epitope spreading. The widest range of antibodies, to both snRNP and hnRNP, is seen in SLE; a more restricted antisplaisosomal antibody repertoire to snRNP and hnRNP is seen in MCTD; and in RA the antisplaisosomal antibody repertoire is restricted to hnRNP.²² In general the autoimmune rheumatic diseases are characterized by the production of autoantibodies that recognize evolutionarily conserved molecules. The mechanism whereby these “hidden” intracellular molecules become autoantigens is an area of ongoing research. The two main theories are apoptotic modification²³ and molecular mimicry.²⁴

Proteins modified during apoptosis can be presented to the immune system in ways that bypass tolerance to self-proteins.⁶ Although rheumatic disease autoantigens are not unified by common structure or function, they have the common feature of becoming clustered and concentrated in the surface blebs of apoptotic cells. A population of smaller blebs contains fragmented endoplasmic reticulum and ribosomes, as well as the ribonucleoprotein Ro. Larger blebs (apoptotic bodies) contain nucleosomal DNA, Ro, La, and the small nuclear ribonucleoproteins.²⁵ During the process of apoptosis several enzyme systems are upregulated with resulting post-translational modifications of the cleaved proteins. These modifications, which include citrullination, phosphorylation, dephosphorylation, transglutamination, and conjugation to ubiquitin, render the molecules more antigenic. For instance, the U1-70K protein is cleaved by the enzyme caspase-3, converting it into a C-terminally truncated fragment, which contains a major B cell epitope that is preferentially recognized by autoimmune sera.²⁶

Figure 86-3 Most proteins in the cytosol and nucleus are degraded via the proteasome-ubiquitin pathway. The 26S proteasome is a huge complex of 2.5 mega-daltons, made up of approximately 35 different subunits. It contains a proteolytic core complex, the 20S proteasome, and one or two 19S regulatory complexes that associate with the termini of the barrel-shaped 20S core. The function of proteasomes is twofold: (1) to degrade intracellular proteins that have been tagged with ubiquitin and (2) to generate antigenic peptides for presentation by the major histocompatibility complex class I molecules. Antibodies to proteasomal subunits have been reported in several autoimmune diseases (especially systemic lupus erythematosus and polymyositis/dermatomyositis), and elevated levels of proteasomes have been correlated with disease activity.

The initial stimulus for a first antibody response may be a *non-self-protein* possessing a peptide region that mimics a self-epitope—so-called molecular mimicry. Environmental stressors such as infection, toxins, drugs, and ultraviolet light may, under some circumstances, induce accelerated apoptosis. A critical limitation to molecular mimicry is the necessity for the antigenic sequence to undergo TCR recognition. Helper T lymphocytes (CD4⁺) usually recognize peptides of 12 to 16 amino acids in the context of HLA class II molecules. However, in some instances smaller peptides may be recognized. They can be *more* immunostimulatory than the parent ligand. Thus antigen recognition by T cells is highly degenerate and expands the potential for molecular mimicry. The universe of molecules containing a pentapeptide, for example, is much greater than for 12 amino residue peptide. Once an immune response to one component of an immunogenic molecular complex has been elicited, other proteins/epitopes of the complex may become antigenic by the same process of epitope spreading.¹⁵

UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

KEY POINTS

Nearly all patients with a UCTD have Raynaud's phenomenon in combination with an unexplained synovitis.

Nail-fold capillary microscopy is useful in evaluating the potential pathology.

Antibody profiles are useful in predicting the eventual clinical features:

- U1-RNP antibodies predict the differentiation into MCTD.
- DNA antibodies predict the differentiation into SLE.
- Nucleolar antibodies predict the differentiation into systemic sclerosis (SSc).

Synthetase and PM/Scl antibodies predict the differentiation into a myositis overlap syndrome.

Rheumatologists frequently see patients who present with a weakly positive ANA and nonspecific symptoms such as arthralgias, fatigue, and cold sensitivity. The critical question in such patients is “will they develop a connective tissue disease?” or “do they have fibromyalgia?”

The answer to this question is not always straightforward because fibromyalgia is not a diagnosis of exclusion²⁷; it is a common comorbidity with the well-defined CTDs and is often associated with cold-induced vasospasm.²⁸ An algorithm for diagnosing UCTDs is given in Figure 86-4. In the early stages of a CTD, there may be just one or two suspicious clinical and laboratory features, but a definitive diagnosis cannot always be made. In such cases a working diagnosis of undifferentiated connective tissue disease (UCTD) may be appropriate.²⁹ Most patients with this UCTD have Raynaud's phenomenon with or without an unexplained polyarthralgia and a positive ANA with usually just a single autoantibody specificity, often anti-Ro and anti-RNP.³⁰ A 5-year follow-up study of 665 patients with UCTD reported that only 34% developed a well-defined CTD (RA—13.1%, Sjögren's—6.8%, SLE—4.2%, MCTD—4%, Scl—2.8%, systemic vasculitis—3.3%, and

PM/DM—0.5%).³¹ Certain combinations of features are predictive for the development of an established CTD: Polyarthritides plus U1-RNP antibodies predict MCTD, sicca symptoms plus anti-SSA/SSB antibodies predict Sjögren's syndrome, Raynaud's phenomenon plus a nucleolar ANA pattern predict Scl, polyarthritides plus high levels of rheumatoid factor (RF) predict RA, and fever/serositis plus a homogeneous ANA pattern or anti-dsDNA antibodies predict progression into SLE (Table 86-2). The identification of a pathologic nail-fold capillary pattern can provide some early indication that the UCTD may progress to systemic sclerosis (SSc) or MCTD (Figure 86-5).³² Low levels of vitamin D are also reported to be a risk factor for the development of UCTDs and should be evaluated and corrected in all such patients.³³

SCLERODERMA OVERLAPS

KEY POINTS

Scleroderma overlap syndromes include scleroderma variants such as calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasia (CREST), myositis associated with sclerodactyly, and MCTD.

Raynaud's phenomenon is often the first clinical feature of SSc overlaps and must be distinguished from primary cold Raynaud's (i.e., cold-induced vasospasm).

The finding of thickened and dilated capillaries on nail-fold microscopy and pathologic autoantibodies (e.g., Scl-70, anticentromere, PM/Scl, U1-RNP) are important clues about the development of an overlap syndrome.

CREST has a common overlap with primary biliary cirrhosis.

Pulmonary fibrosis and pulmonary hypertension are the main causes of morbidity/mortality.

Scleroderma-like disorders (e.g., eosinophilic fasciitis, scleromyxedema, nephrogenic fibrosis, scleredema) need to be considered in the differential diagnosis of scleroderma overlaps.

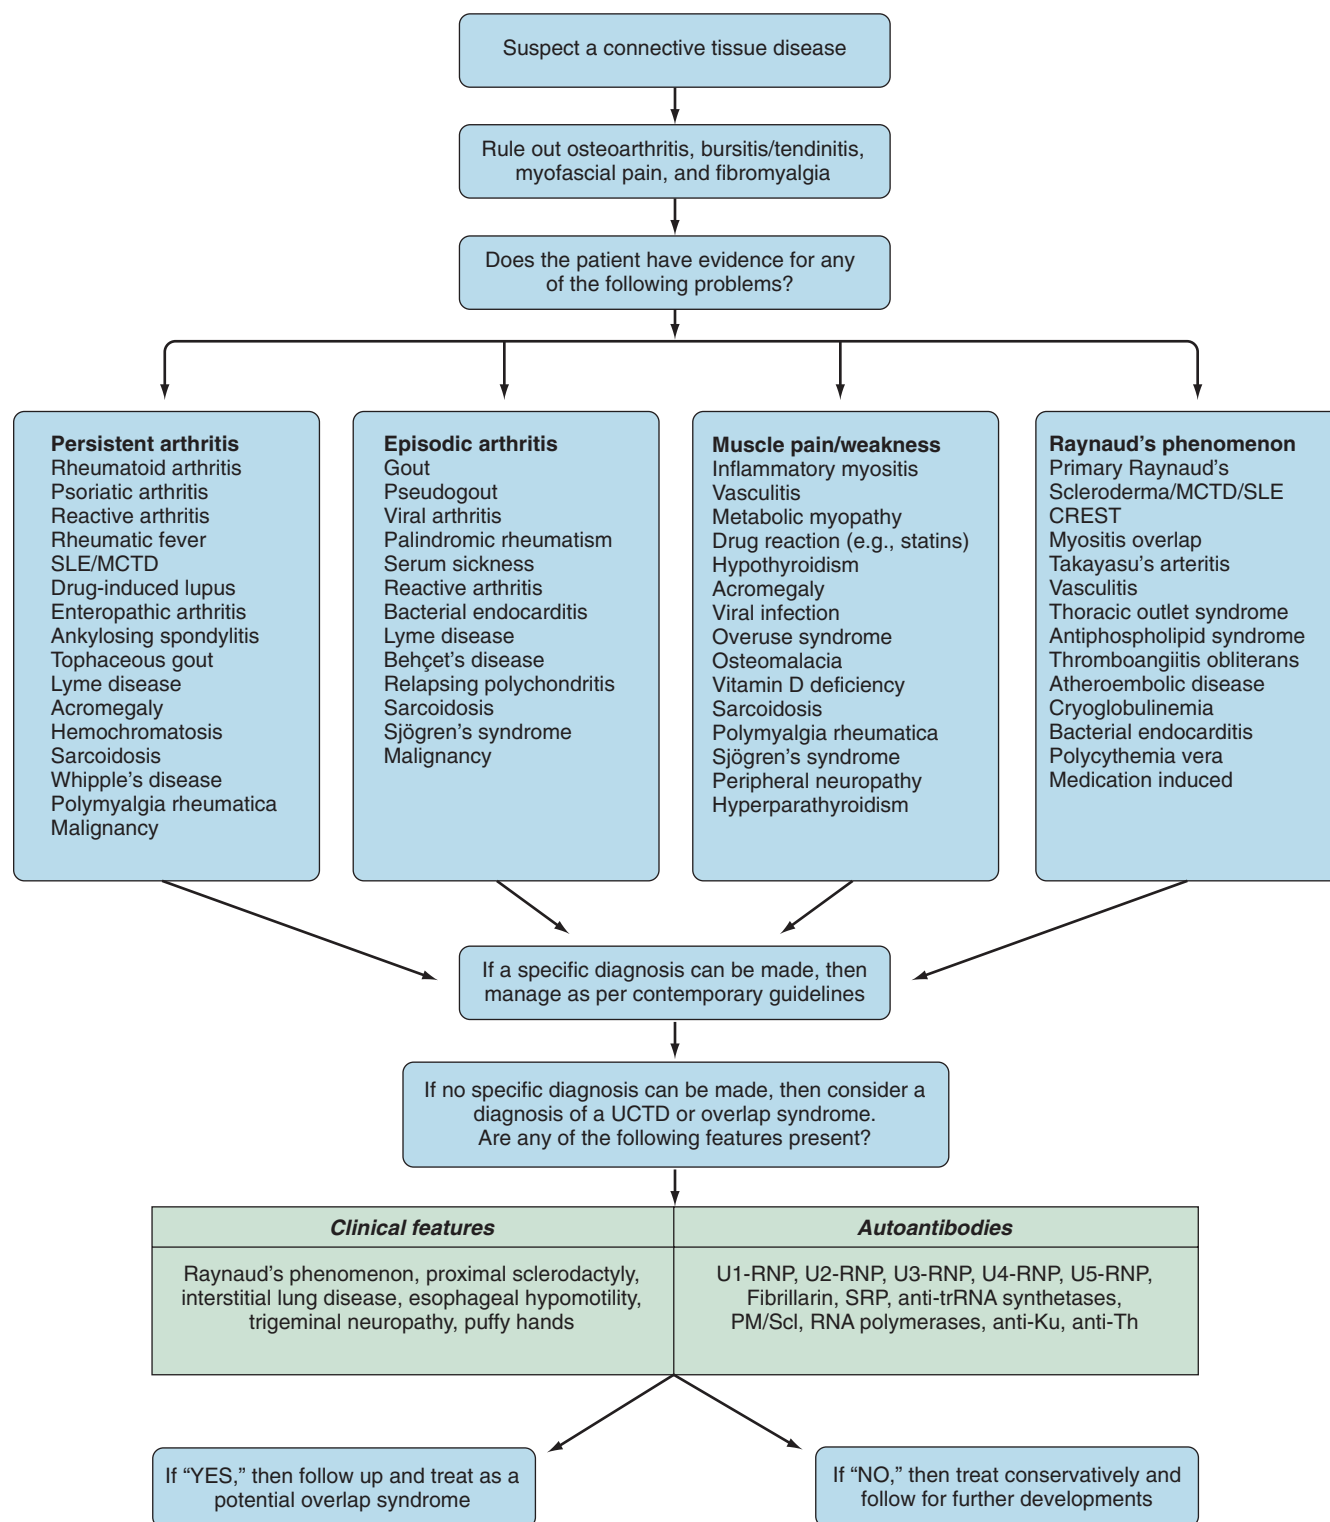

Figure 86-4 Algorithm for evaluating patients with undifferentiated connective tissue disease (UCTD). CREST, calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus.

Several fibrotic conditions may mimic scleroderma (see Table 86-2). Scleroderma itself has a widespread heterogeneity of disease expression ranging from a diffuse cutaneous disease, with a poor prognosis, to a limited cutaneous involvement, with generally a good prognosis. Furthermore, some patients with Scl have a prominent overlap with other

connective tissue diseases.³⁴ In many cases, these overlaps occur in patients who do not have prominent skin involvement (sine scleroderma) or with the limited form of the disease—CREST. Approximately 90% of patients with Scl have a positive ANA. Scleroderma-related antibodies include topoisomerase I (Scl-70), anticentromere (ACA),

Figure 86-5 Nail-fold capillaroscopy in patients with systemic sclerosis and mixed connective tissue disease (MCTD). **A**, Normal capillaries. **B**, MCTD patient showing dilated and thickened capillary loops. **C**, Early scleroderma with irregular capillaries and mild dropout. **D**, Advanced scleroderma with capillary dropout and neoangiogenesis. (Modified from Cutolo M, Sulli A, Pizzorni C, Smith V: *Capillaroscopy as an outcome measure for clinical trials on the peripheral vasculopathy in SSc—is it useful?* Int J Rheumatol pii:784947, 2010.)

hnPNP-I, RA33, p23, p25, RNA polymerase I (RNAP-1), RNA polymerase III, U1-RNP, PM/Scl, fibrillarin, histone, Ku, endothelial cell, and Th/To³⁵ (see Table 86-1).

A German registry for scleroderma has reported on patterns of organ involvement in two subsets of 1483 SSc patients.³⁶ Limited distal skin involvement (distal to the knee and elbows) was seen in 46% (the lcSSc group), and 33% had progressive widespread scleroderma (rapid involvement of trunk, face, and extremities—the dcSSc group). An overlap syndrome was seen in 11%, and 8% were undifferentiated. The extent of organ involvement varied between subgroups. For instance, musculoskeletal involvement was seen in 68% of the overlap group compared with 57% of the dcSSc group. Pulmonary fibrosis (56%) and pulmonary hypertension (19%) were most common in the dcSSc group, but pulmonary hypertension was seen in 15% of the lcSSc group.

Specific antibody profiles tend to be associated with distinctive patterns of morbidity and mortality.³⁷ Patients possessing anticentromere, anti-U3 snRNP, and anti-Th/To antibodies tend to have the limited form of Scl, whereas anti-Scl-70, ACA, and anti-RNAP are associated with

diffuse skin involvement and systemic disease. Anti-PM/Scl antibodies are associated with a myositis/Scl overlap and a tendency to develop pulmonary interstitial disease.³⁸ About 60% of patients with scleroderma have obvious synovitis, and 35% are positive for RF. Erosive arthritis in Scl has an association with anti-RA33; the Scl component in such overlap patients is often an incomplete form of CREST.³⁹ The limited form of scleroderma has a well-documented overlap with primary biliary cirrhosis (PBC). The distinctive antibody association of scleroderma with PBC is anti-mitochondrial antibodies.⁴⁰ Conversely, anticentromere antibodies have been found in 10% to 29% of patients with PBC; approximately half developed some features of the CREST syndrome. Hence a serologic overlap between the two syndromes is more prevalent in the clinical overlap. Low-grade muscle involvement is not uncommon in scleroderma, being described in between 50% and 80% of patients. A European review of 114 scleroderma overlap patients reported a 95% PM/Scl antibody positivity⁴¹ with 80% having an inflammatory myositis. This “scleromyositis” differed from MCTD by coexistent features of dermatomyositis (myalgia, myositis, Gottron sign, heliotrope rash,

calcinosis), but no overlap SLE features, as is characteristic of classic MCTD. Many of these patients had a deforming arthritis of the hands. In general they had a chronic benign course, and most were steroid responsive. Scleroderma lupus overlaps are less common. However, Scl patients often have antinuclear antibodies other than ACA and Scl-70.

Nonscleroderma fibrotic disorder may be mistaken for a scleroderma overlap at initial presentation (see Table 86-2); although these disorders may have some systemic involvement, they seldom exhibit overlap features with other AICTDs.

Nephrogenic systemic fibrosis (NSF) is a fibrotic disorder that develops in some patients following exposure to gadolinium-containing contrast agents; most patients have pre-existing renal disease.⁴² Histologically there is fibroblast proliferation, thickened collagen bundles, and deposits of mucin, similar to those observed in scleromyxedema. The clinical presentation is a rapid progression with confluence of initially focal areas of indurated skin (Figure 86-6). The face is usually spared, but joint contractures may occur at the elbows and knees, and systemic involvement with pulmonary and neurologic symptoms can develop in refractory

cases. NSF is usually nonresponsive to corticosteroids and immunosuppressive therapy.

Eosinophilic fasciitis presents with limited scleroderma-like skin changes involving the extremities (see Figure 86-6). The correct diagnosis is suggested by finding a peripheral eosinophilia and a hypergammaglobulinemia.⁴³ The definitive diagnosis is established by a full-thickness skin biopsy that shows a diffuse inflammation of the fascia. Initial treatment is with corticosteroids (prednisone 0.5 to 1 mg/kg) tapering according to the clinical response; some patients need to continue moderate-dose corticosteroids for up to 2 years. Methotrexate and mycophenolate may be used in refractory cases.

Scleromyxedema is characterized by cutaneous mucinosis and is often associated with a gammopathy, usually IgM and light chains.⁴⁴ The mucinous skin lesions appear as waxy papules on the face, neck, and limbs. If the papules coalesce, it may be mistaken for scleroderma (see Figure 86-6). Systemic involvement may occur with dysphagia, proximal muscle weakness, pulmonary, cardiac, and renal complications. It is difficult to manage; corticosteroids are usually tried initially, in refractory cases some benefit has

Figure 86-6 Four examples of fibrosing disorders. **A**, Scleromyxedema (mucinous skin lesions appear as waxy papules on the face). **B**, Eosinophilic fasciitis (induration of skin and subcutaneous tissues). **C**, Scleredema (diffuse subcutaneous edema with swelling over right trapezius). **D**, Nephrogenic systemic fibrosis (coalescence of indurated nodules with joint contracture). (Modified from Boin F, Hummers LK: Scleroderma-like fibrosing disorders, *Rheum Dis Clin North Am* 34:199–220, 2008.)

been reported for intravenous immunoglobulin and thalidomide.

Scleredema is a cutaneous mucinosis that often starts with a febrile episode and resolves spontaneously.⁴⁵ More chronic scleredema has been associated with paraproteinemias including multiple myeloma and diabetes mellitus. The dermis is thickened with increased collagen glycosylation, as in diabetic stiff skin syndrome. The face and neck are commonly involved, and there is relative sparing of the hands and feet (see Figure 86-6). Systemic organ involvement is rare, but a monoclonal gammopathy is sometimes seen. Such cases need to be worked up for lymphoma. Refractory cases have been helped by local radiotherapy.

MYOSITIS OVERLAPS

KEY POINTS

Myositis overlap syndromes are more common than the classic descriptions of PM or DM.

Amino-acyl tRNA synthetase antibodies (ARS) are associated with myositis, arthritis, and interstitial lung disease.

Arthritis and interstitial lung disease may antedate the appearance of myositis in patients with ARS.

Antibodies to synthetases, signal recognition particle (SRP), and nucleoporin tend to be associated with corticosteroid unresponsiveness.

Antibodies to U1-RNP, PM/Scl, or Ku are associated with corticosteroid responsiveness.

Antibodies to 155-kD and 140-kD proteins have been associated with an increased risk of myositis-associated malignancy.

Polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM) are the classic idiopathic inflammatory myopathies (IIM), yet the same clinical picture and investigational findings may be found in patients with SLE, Scl, MCTD, and Sjögren's syndrome. Such overlaps, especially with scleroderma, have been reported as being more common in the classic description of polymyositis.⁴ When clinical overlaps emerge, they are most commonly associated with specific autoantibodies, namely anti-PM-Scl, anti-Ku, U1-RNP, Jo-1, SRP, and ARS.⁴⁶ The arthropathy associated with polymyositis is characterized by deforming subluxations (particularly of the distal interphalangeals and thumbs) with only minor erosive changes. Another myositis overlap syndrome is seen in patients with amino-acyl tRNA synthetase antibodies (ARS).⁴⁷ This is a family of enzymes that catalyze the transfer of a specific amino acid to its cognate transfer RNA—the commonest association is with anti-Jo-1 (histidine-tRNA synthetase). The clinical syndromes associated with the various antisynthetase antibodies are similar, with remissions and exacerbations characterized by inflammatory myositis, fever, Raynaud's syndrome, and skin problems (mechanic's hands).⁴⁸ The arthritis of ARS may initially mimic RA with an inflammatory arthritis and nodules; erosions, however, do not occur.⁴⁹ Interstitial lung disease may be a presenting clinical feature of patients with ARS antibodies, with myopathy occurring

much later. The association of myositis in patients with anti-U1-RNP antibodies is usually seen in the context of MCTD.⁵⁰ Antibodies to the signal recognition particle (SRP) have been reported in 4% of patients with Scl/PM overlap; these patients usually have a severe, rapidly progressive myositis with prominent muscle fiber necrosis without much inflammatory cell infiltration.⁵¹

A 2006 clinical and longitudinal study of 100 consecutive French Canadian patients with idiopathic IIM concluded that the original Bohan and Peter classification of inflammatory myopathies should be abandoned because 60% of patients with IIM were found to have an overlap syndrome.⁴ In this study an overlap syndrome was based on the presence of an inflammatory myopathy as per the Bohan and Peter classification,⁵² plus at least one clinical overlap feature (Table 86-3), or one of the following autoantibodies: synthetases, centromere, topo I, RNA-polymerases I or III, Th, U1-RNP, U2-RNP, U3-RNP, U5-RNP, PM/Scl, Ku, SRP and nucleoporins (see Table 86-3). The distinction between classic PM/DM and an overlap syndrome was reported to be of prognostic/therapeutic significance because classic PM nearly always pursued a chronic course with 50% of patients being initially unresponsive to corticosteroid therapy. Pure dermatomyositis was almost always chronic, but most had an initial response to corticosteroids. On the other hand, myositis overlap syndromes (usually with scleroderma features) were almost always responsive to corticosteroids (~90% response rate). When overlap patients were divided according to antibody subsets, antisynthetase, SRP, and nucleoporin autoantibodies were markers for treatment-resistant myositis, whereas autoantibodies to U1-RNP, PM/Scl, or Ku were markers for corticosteroid responsiveness. Patients with autoimmune myositis, especially dermatomyositis, are at risk of developing cancer,⁵³ and it has been problematic as to how far and how often one should pursue a malignancy workup. It is now apparent that the finding of an antibody against 155-kD and 140-kD protein specificities (anti-155/140 antibody) signifies a significant risk for the co-occurrence of a malignancy and points to the need for a thorough cancer workup.⁵⁴

MIXED CONNECTIVE TISSUE DISEASE

KEY POINTS

The clinical overlap features of MCTD (i.e., Scl, SLE, and IIM) seldom occur concurrently but develop sequentially over the course of months or years.

Raynaud's phenomenon is seen in nearly all patients with MCTD; if Raynaud's syndrome is absent, the diagnosis should be reconsidered.

About 25% of MCTD patients develop renal involvement—usually membranous glomerulonephritis. Proliferative glomerulonephritis is uncommon in MCTD.

Serious CNS involvement is rare in MCTD; the commonest findings are trigeminal neuropathy and sensorineural hearing loss.

Pulmonary hypertension is the commonest cause of death in MCTD patients and should be screened for on an ongoing basis.

Table 86-3 Suggested Classification for Inflammatory Myopathies

Abbreviation	Description
PM	Pure polymyositis
DM	Pure dermatomyositis
OM	Overlap myositis: myositis with at least 1 clinical overlap feature and/or an overlap autoantibody
CAM	Cancer-associated myositis: with clinical paraneoplastic features and without an overlap autoantibody or anti-Mi-2
Bohan and Peter's⁵² Definition of Myositis	
1. Symmetric proximal muscle weakness. 2. Elevation of serum skeletal muscle enzymes. 3. Electromyographic triad of short, small, polyphasic motor unit potentials; fibrillations, positive sharp waves, and insertional irritability; and bizarre, high-frequency repetitive discharges. 4. Muscle biopsy abnormalities of degeneration, regeneration, necrosis, phagocytosis, and an interstitial mononuclear infiltrate. 5. Typical skin rash of DM including the heliotrope rash, Gottron sign, and Gottron papules.	
Definite myositis: 4 criteria (without the rash) for PM, 3 or 4 criteria (plus the rash) for DM. Probable myositis: 3 criteria (without the rash) for PM, 2 criteria (plus the rash) for DM. Possible myositis: 2 criteria (without the rash) for PM, 1 criterion (plus the rash) for DM.	
Definition of Clinical Overlap Features	
Inflammatory myopathy plus at least 1 or more of the following clinical findings: polyarthritis, Raynaud's phenomenon, sclerodactyly, scleroderma proximal to metacarpophalangeal joints, typical SSC-type calcinosis in the fingers, lower esophageal or small-bowel hypomotility, DLCO lower than 70% of the normal predicted value, interstitial lung disease on chest radiogram or computed tomography scan, discoid lupus, anti-native DNA antibodies plus hypocomplementemia, 4 or more of 11 American College of Rheumatology criteria for systemic lupus erythematosus, antiphospholipid syndrome.	
Definition of Overlap Autoantibodies	
Antisynthetases (Jo-1, PL-7, PL-12, OJ, EJ, KS); scleroderma-associated autoantibodies (scleroderma-specific antibodies: centromeres, topoisomerase I, RNA polymerases I or III, Th; and antibodies associated with scleroderma overlap: U1-RNP, U2-RNP, U3-RNP, U5-RNP, Pm-Scl, Ku, and other autoantibodies (signal recognition particle, nucleoporins).	
Definition of Clinical Paraneoplastic Features	
Cancer within 3 yr of myositis diagnosis, plus absence of multiple clinical overlap features; plus, if cancer was cured, myositis was cured as well.	

Modified from Troyanov Y, Targoff IN, Tremblay JL, et al: Novel classification of idiopathic inflammatory myopathies based on overlap syndrome features and autoantibodies: analysis of 100 French Canadian patients, *Medicine (Baltimore)* 84:231–249, 2005.

MCTD was described by Sharp and colleagues⁵⁵ in a 1971 paper reporting an overlap of SLE, Scl, and PM. This was the first overlap syndrome defined in terms of a specific antibody—namely antibodies to a ribonuclease-sensitive extractable nuclear antigen (ENA). Over the past 38 years, many studies have explored the clinical correlates of this antibody system (now called U1-RNP).

Serologic Features

The basic premise of the MCTD concept is that the presence of high-titer anti-U1-RNP antibodies modifies the expression of an AICTD in ways that are relevant to prognosis and treatment.⁵⁶ The first clue to diagnosing MCTD is usually a positive ANA with a high-titer speckled pattern. The titer is often greater than 1:1000 and sometimes greater than 1:10,000. This finding should prompt the measurement of antibodies to U1-RNP, Sm, Ro, and La. It is also pertinent to note whether the serum contains antibodies to dsDNA and histones because patients destined to follow a course most consistent with MCTD have sera with predominant U1-RNP reactivity. Antibodies to dsDNA, Sm, and Ro are occasionally seen as a transient phenomenon in patients with MCTD. But when they are found consistently, as the predominant antibody system, the clinical picture is usually more consistent with classic SLE. Antibodies to the 70-kD antigen, especially in its apoptotic form, are most closely associated with the clinical correlates of MCTD.⁸

Clinical Features

Diagnosis

MCTD is an overlap syndrome that embraces features of SLE, Scl, and PM/DM.⁵⁷ These overlap features seldom occur concurrently; it usually takes several years before enough overlapping features have appeared to be confident that MCTD is the most appropriate diagnosis.⁵⁸ The commonest clinical associations with U1-RNP antibodies in the early phase of the disease are hand edema, arthritis, Raynaud's phenomenon, inflammatory muscle disease, and sclerodactyly. No American College of Rheumatology (ACR) criteria are available for the diagnosis of MCTD, but a comparative study reported that two criteria sets, those of Alarcon-Segovia and Kahn, had the best sensitivity and specificity (62.5% and 86.2%, respectively)⁵⁹ (Table 86-4). The sensitivity could be improved to 81.3% if the term "myalgia" was substituted for "myositis."⁶⁰ Some patients initially diagnosed as MCTD will evolve into a clinical picture most consistent with SLE or RA; in one long-term follow-up, more than half of the subjects continued to satisfy criteria for MCTD.⁶¹ A comparison of the clinical and serologic features of MCTD with SLE, RA, Scl, and PM/DM is given in Table 86-5.

Early Symptoms

In the early stages most patients destined to develop MCTD cannot be differentiated from the other classic AICTDs.

Table 86-4 Diagnostic Criteria for Mixed Connective Tissue Disease

	Alarcón-Segovia Criteria	Kahn Criteria
Serologic criteria	Anti-RNP at hemagglutination titer of $\geq 1:1600$	High-titer anti-RNP corresponding to a speckled ANA of $\geq 1:1200$ titer
Clinical criteria	<ol style="list-style-type: none"> 1. Swollen hands 2. Synovitis 3. Myositis (biologically proven) 4. Raynaud's phenomenon 5. Acrosclerosis 	<ol style="list-style-type: none"> 1. Swollen fingers 2. Synovitis 3. Myositis 4. Raynaud's phenomenon
MCTD present if:	Serologic criterion accompanied by 3 or more clinical criteria, one of which must include synovitis or myositis	Serologic criterion accompanied by Raynaud's phenomenon and 2 or more of the 3 remaining clinical criteria

ANA, antinuclear antibody; MCTD, mixed connective tissue disease; RNP, ribonucleoprotein particle.

From Alarcon-Segovia D, Cardiel MH: Comparison between 3 diagnostic criteria for mixed connective tissue disease. Study of 593 patients, *J Rheumatol* 16(3):328–334, 1989.

The assumption that a diagnosis of MCTD implies a *simultaneous* presence of features usually seen in SLE, Scl, and PM is erroneous. It is unusual to see such an overlap during the early course of MCTD, but with the progress of time the overlapping features usually occur sequentially. Early in the course of the disease most patients complain of easy fatigability, poorly defined myalgias, arthralgias, and Raynaud's phenomenon; at this point in time a diagnosis of RA, SLE, or undifferentiated connective tissue disease (UCTD) seems most appropriate.¹ If such a patient is found to have swollen hands or puffy fingers (Figure 86-7) in association with a high-titer speckled ANA, he or she should be carefully followed for the evolution of overlap features (see Table 86-3). A high titer of anti-RNP antibodies in a patient with UCTD is a powerful predictor for a later evolution into MCTD, which gives little clue to the subsequent course; such presentations have included polymyositis, acute arthritis, aseptic meningitis, digital gangrene, high fever, acute abdomen, and trigeminal neuropathy.⁶²

Fever

Fever may be a prominent feature of MCTD in the absence of an obvious cause. Fever of unknown origin has been the initial presentation of MCTD; after careful evaluation, fever in MCTD can usually be traced to a coexistent myositis, aseptic meningitis, serositis, lymphadenopathy, or intercurrent infection.

Joints

Joint pain and stiffness is an early symptom in nearly all patients who develop the MCTD syndrome. Over the past 2 decades it has become increasingly apparent that joint involvement in MCTD is more common and more severe than in classic SLE.⁶³ About 60% of patients eventually develop an obvious arthritis, often with deformities commonly seen in RA such as ulnar deviation, swan neck, and boutonnière changes.⁶⁴ Radiographs usually show a characteristic absence of severe erosive changes; they often

MCTD, mixed connective tissue disease; PM, polymyositis; RA, rheumatoid arthritis; Scl, scleroderma; SLE, systemic lupus erythematosus.

Figure 86-7 The hand of a man with mixed connective tissue disease. The fingers have a generally puffy appearance with a fusiform proximal interphalangeal swelling of the third finger from an inflammatory arthritis. There is a periungual infarct at the nail fold of the third finger. (Modified from Pope JE: *Other manifestations of mixed connective tissue disease*, *Rheum Dis Clin North Am* 31:519–533, 2005.)

resemble Jaccoud's arthropathy. However, a destructive arthritis including an arthritis mutilans is a well-established association.⁶⁴ Small marginal erosions, often with a well-demarcated edge, are the most characteristic radiologic features in patients with severe joint disease.⁶⁵ Some patients

develop a flexor tenosynovitis, bone edema, and pericapsular inflammation reminiscent of a seronegative spondyloarthropathy (Figure 86-8). A positive RF is found in 50% to 70% of patients; indeed, patients may be diagnosed as having RA and fulfill ACR criteria for RA.

Skin and Mucous Membranes

Most patients with MCTD develop mucocutaneous changes sometime during the course of the syndrome. Raynaud's phenomenon is the commonest problem and one of the earliest manifestations of MCTD.⁶⁶ It may be accompanied by puffy, swollen digits and sometimes total hand edema.⁶² In some patients, skin changes commonly associated with classic SLE are prominent findings, particularly malar rash and discoid plaques. Other problems have included buccal ulceration, sicca complex, orogenital ulceration, livedo vasculitis, subcutaneous nodules, and nasal septal perforation.

Muscle

Myalgia is a common symptom in patients with the MCTD syndrome. In most patients there is no demonstrable weakness, EMG abnormalities, or muscle enzyme changes. It is often unclear whether the symptom represents a low-grade myositis, physical deconditioning, or an associated

Figure 86-8 Hand magnetic resonance images of two females aged 25 and 32 with mixed connective tissue disease and hand arthritis. **A**, Patient 1 has synovitis/effusion around the ulnar styloid (asterisk) and tenosynovitis of the flexor and extensor tendons (arrows) (T1-weighted gadolinium-enhanced sequence on axial plane). **B**, Patient 2 has intense synovitis of the radioulnar joint (asterisk) and extensor tenosynovitis (arrows) causing thickening of the dorsum of the hand (T1-weighted short tau inversion recovery [STIR] sequence on axial plane). **C**, Patient 1 has synovitis/effusion, and pericapsular edema is seen in the second proximal interphalangeal joint. The distended capsule is indicated by arrows. **D**, Patient 2 has intracapsular synovial effusion or synovitis of the third and fourth metacarpophalangeal joints (arrows). (Both **C** and **D** are T1-weighted STIR sequences in the coronal plane.) (From Cimmino MA, Lozzelli A, Garlaschi G, et al: *Magnetic resonance imaging of the hand in mixed connective tissue disease*, *Ann Rheum Dis* 62:380–381, 2003.)

Figure 86-9 Muscle biopsy from the biceps brachii of a mixed connective tissue disease patient (H&E stain, $\times 300$). **A**, Moderate variation of fiber size and degenerated fibers (\rightarrow) with mononuclear cell infiltration. **B** and **C** show perivascular inflammatory infiltration and thickening of vessel walls. (Modified from Vianna M, Borges MT, Borba EF, et al: Myositis in mixed connective tissue disease: a unique syndrome characterized by immuno-histopathologic elements of both polymyositis and dermatomyositis, *Arq Neuro-Psiquiatr* 62:923–934, 2004.)

fibromyalgia syndrome. The inflammatory myopathy associated with MCTD is similar histologically to IIM, with features of both the vascular involvement of DM and the cell-mediated changes of PM⁶⁷ (Figure 86-9). In most patients myositis occurs as an acute flare against a background of general disease activity. Such patients usually respond well to a short course of high-dose corticosteroid therapy. Another scenario is that of a low-grade inflammatory myopathy, which is often insidious in its onset; these patients often have a poor therapeutic response to corticosteroids. Some patients with PM associated with MCTD develop an impressive fever⁶²; other patients may give a history of febrile myalgias that were diagnosed as “flu.”

Heart

All three layers of the heart may be involved in MCTD.⁶⁸ An abnormal electrocardiogram (ECG) is noted in about 20% of patients. The most common ECG changes are right ventricular hypertrophy, right atrial enlargement, and inter-ventricular conduction defects. Pericarditis is the commonest clinical manifestation of cardiac involvement, reported in 10% to 30% of patients. Pericardial tamponade is rare. Involvement of the myocardium is increasingly recognized. In some patients myocardial involvement is secondary to

pulmonary hypertension (PAH); this occurs in some 20% of patients and is often asymptomatic in its early stages.⁶⁹ The early detection of pulmonary hypertension is increasingly important because there are now more effective therapeutic options. PAH is probably underdiagnosed in its early stages; in a community rheumatology practice setting an elevation of the estimated right ventricular systolic pressure (ERVSP), consistent with the diagnosis of PAH, was found in 13% of previously undiagnosed subjects.⁷⁰ This diagnosis should be suspected in patients with increasing exertional dyspnea. Two-dimensional echocardiography with Doppler flow studies is the most useful screening test, with a definitive diagnosis requiring cardiac catheterization showing a mean resting pulmonary artery pressure greater than 25 mm Hg at rest. The development of pulmonary hypertension has been correlated with a nail-fold capillary pattern similar to that seen in Scl, antiendothelial cell antibodies, anticardiolipin antibodies, and anti-U1-RNP antibodies.⁷¹ Both left and right ventricular dysfunction appears to be a common finding that is not always associated with PAH; regular echocardiographic evaluations are recommended for all MCTD patients, especially those with PAH. Elevated levels of anti-U1-RNP antibodies, antiendothelial cell antibodies, serum thrombomodulin, and Willebrand factor are prognostic clues to the development of PAH.⁷²

Figure 86-10 Computed tomography scans of a patient with mixed connective tissue disease and pulmonary hypertension (**A**, upper zones; **B**, lower zones). There are bilateral pleural effusions and enlarged bilateral mediastinal lymph nodes in the right paratracheal region and left perivascular areas. The pulmonary artery has a diameter greater than that of the ascending aorta—consistent with the diagnosis of pulmonary hypertension. Both hilar pulmonary arteries are also enlarged. A fairly large pericardial effusion is present. The lung windows show evidence of a diffuse abnormality with linear opacities and some areas of ground-glass attenuation in the upper zones. At the lung bases there are more confluent opacities, both reticular and ground glass, and some air-space consolidation. No honeycombing is identified, and there is no distortion of the lung architecture. (From Saito Y, Terada M, Ishida T, et al: *Pulmonary involvement in mixed connective tissue disease: comparison with other collagen vascular diseases using high resolution CT*, *J Comput Assist Tomogr* 26:349–357, 2002.)

Lung

Lung involvement occurs in up to 75% of patients.⁷³ Early symptoms that should prompt further investigations are dry cough, dyspnea, and pleuritic chest pain.⁷⁴ Interstitial lung disease (ILD) occurs in up to 50% of subjects. High-resolution computed tomography (HRCT) is the most sensitive test to determine the presence of ILD (Figure 86-10).⁷⁵ The commonest HRCT findings are septal thickening and ground-glass opacities. Untreated ILD is usually progressive with the development of severe pulmonary fibrosis in 25% of subjects after 4 years of follow-up.⁷⁶ Pulmonary hypertension (PAH) is prognostically the most severe form of pulmonary involvement in MCTD. Unlike Scl, where pulmonary hypertension is often secondary to an interstitial pulmonary fibrosis, PAH in MCTD is usually caused by a bland intimal proliferation and medial hypertrophy of pulmonary arterioles⁷⁷ (Figure 86-11).

Kidney

In the initial description of MCTD, renal involvement was considered to be rare.⁵⁷ After some 4 decades of observations, it is now evident that renal involvement occurs in about 25% of patients.⁷⁸ However, high titers of anti-U1 RNP antibodies are relatively protective against the development of diffuse proliferative glomerulonephritis, irrespective of whether they occur in a setting of classic SLE or MCTD. When patients with MCTD do develop renal changes, it usually takes the form of a membranous glomerulonephritis.⁷⁹ This is often asymptomatic but may sometimes cause an overt nephrotic syndrome.⁸⁶ The development of diffuse proliferative glomerulonephritis or parenchymal interstitial disease has been rarely recorded in MCTD. There is increasing recognition that MCTD patients are at risk of developing a renovascular hypertensive crisis similar to the scleroderma kidney.

Gastrointestinal

Gastrointestinal involvement is a major feature of the overlap with scleroderma, occurring in about 60% to 80% of patients.⁶³ The commonest abdominal problem in MCTD is disordered motility in the upper gastrointestinal tract. There have been case reports of hemoperitoneum, hemato-bilia, duodenal bleeding, megacolon, pancreatitis, ascites, protein-losing enteropathy, primary biliary cirrhosis, portal hypertension, pneumatosis intestinalis, and autoimmune hepatitis.⁸⁰ Abdominal pain in MCTD may result from

Figure 86-11 Intimal hyperplasia and smooth muscle hypertrophy without accompanying inflammation are the characteristic features of the vasculopathy of mixed connective tissue disease. When it occurs in the lung, as shown here, it may give rise to severe pulmonary hypertension. (Note absence of pulmonary fibrosis.) The plexiform lesion (arrow) is a characteristic pathologic finding in this disease process. (From Bull TM, Fagan KA, Badesch DB: *Pulmonary vascular manifestations of mixed connective tissue disease*, *Rheum Dis Clin North Am* 31:451–464, 2005.)

bowel hypomotility, serositis, mesenteric vasculitis, colonic perforation, and pancreatitis. Malabsorption syndrome can occur secondarily to small bowel dilation with bacterial overgrowth. Liver involvement in the form of chronic active hepatitis and Budd-Chiari syndrome has been described. Pseudodiverticula, identical to those seen in SCC, may be seen along the antimesenteric border of the colon.

Nervous System

In keeping with Sharp's original description, CNS involvement has not been a conspicuous feature of MCTD. The commonest problem is a trigeminal neuropathy.⁸¹ In a review of 81 cases of trigeminal neuropathy seen in a neurologic clinic, the most frequently associated CTDs were undifferentiated connective tissue disease (47%), mixed connective tissue disease (26%), and scleroderma (19%). A sensorineural hearing loss has been reported in nearly 50% of MCTD patients.⁸² In contrast to CNS involvement in classic SLE, frank psychosis and convulsions have rarely been reported in MCTD.⁸¹ Headaches are a relatively common symptom; in the majority of patients they are vascular in origin with many of the components of classic migraine. In a subset of these patients, signs of meningeal irritation develop and examination of the cerebrospinal fluid (CSF) reveals the changes of aseptic meningitis.⁸³ Aseptic meningitis in MCTD has also been described as a hypersensitivity reaction to nonsteroidal anti-inflammatory drugs, in particular sulindac and ibuprofen. There are isolated reports of transverse myelitis, cauda equina syndrome, cerebral hemorrhage, retinal vasculitis, optic neuropathy, progressive multifocal leukoencephalopathy, cold-induced

brain ischemia, myasthenia gravis, polyradiculopathy, demyelinating disorder, and peripheral neuropathy. Elevated CSF levels of anti-U1-RNP antibodies, with a predominance of anti-70-kD antibodies, have been reported in both SLE and MCTD patients with diffuse central neuropsychiatric involvement.⁸⁴ Many patients with AICTDs have changes on brain magnetic resonance imaging that are referred to as unspecific bright objects (UBOs). In many instances UBOs occur in the absence of neurologic symptoms. However, there is a modest correlation between the density and positioning of UBOs; in MCTD these lesions tend to cluster at the corticomedullary junction and periventricular region.⁸⁵

Blood Vessels

Raynaud's phenomenon is an early feature of nearly all patients who are eventually diagnosed as having MCTD.⁶⁶ A bland intimal proliferation and medial hypertrophy affecting medium- and small-sized vessels is the characteristic vascular lesion of MCTD⁸⁶ (see [Figure 86-11](#)) and is the characteristic pathology in pulmonary hypertension and renovascular crises. Both nail-fold capillary microscopy⁸⁷ and color Doppler⁸⁸ are useful in distinguishing benign primary Raynaud's from secondary involvement in MCTD and other AICTDs (see [Figure 86-5](#)). Fingernail capillaroscopy is abnormal in most MCTD patients with the same pattern of capillary dilation and dropout that has been reported in Scl.⁸⁹ An angiographic study reported a high prevalence of medium-size vessel occlusions⁹⁰ ([Figure 86-12](#)). Endothelial cell and anticardiolipin antibodies have been reported to be associated with endothelial dysfunction and the development of atherosclerosis in MCTD.⁹¹

Figure 86-12 **A**, Digital angiogram showing multiple arterial occlusions with collateral formation. **B**, Digital angiogram showing ulnar artery occlusions. (From Peller JS, Gabor GT, Porter JM, Bennett RM: Angiographic findings in mixed connective tissue disease: correlation with fingernail capillary photomicroscopy and digital photoplethysmography findings, *Arthritis Rheum* 28:768, 1985. Reprinted with permission of the American College of Rheumatology.)

Blood

Hematologic abnormalities are a common finding in MCTD. Anemia is found in 75% of patients, and the usual profile is most consistent with the anemia of chronic inflammation.⁶³ A positive Coombs test is seen in about 60% of patients, but an overt hemolytic anemia is uncommon.⁹² As in SLE, a leukopenia affecting mainly the lymphocyte series is seen in about 75% of patients and tends to correlate with disease activity. Less common associations have been thrombocytopenia, thrombotic thrombocytopenia purpura, and red cell aplasia. Hypocomplementemia has been described in several studies⁶³; it is not as prevalent as in classic SLE and has not been correlated with any particular clinical situation. Positive tests for RF have been found in about 50% of patients.⁹³ The presence of RF is associated with more severe degrees of arthritis, especially if anti-A2/RA33 are also present.¹¹ Anticardiolipin antibodies or lupus anticoagulants, or both, have also been reported. Unlike the anticardiolipin antibodies found in SLE, they are β 2-glycoprotein independent and tend to be associated with thrombocytopenia rather than thrombotic events.⁹⁴

Pregnancy

Reports of maternal and fetal morbidity in MCTD are quite diverse.⁹⁵ In a comparison study of patients with MCTD and SLE, the fertility rates in both diseases were unaltered, whereas the parity and fetal wastage was increased in both.⁹⁶ Some studies have reported an exacerbation of MCTD during pregnancy and postpartum flares,⁹⁶ whereas others have not. Antiendothelial antibodies have been linked to spontaneous abortion in MCTD.⁹⁷ A single case of neonatal “lupus” has been reported, suggesting a pathogenic role for the transplacental passage of anti-U1-RNP antibodies.⁹⁸

Juvenile Mixed Connective Tissue Disease

MCTD may first become apparent in childhood. The average age of onset in one report was 10.7 years.⁹⁹ Polyarthritis and Raynaud's phenomena are the most common presenting features. There tends to be a progression of organ involvement with 20% involvement at 5 years and 48% at 10 years. Significant myocarditis, glomerulonephritis, thrombocytopenia, seizures, hemolytic uremic syndrome, an acute coronary syndrome, and aseptic meningitis have been described in isolated cases.

MANAGEMENT OF CONNECTIVE TISSUE DISEASE OVERLAPS

The rational management of overlap CTDs is confounded by the absence of controlled trials. Recommendations for management are based on conventional treatments for SLE, PM/DM, RA, and Scl.¹⁰⁰ General guidelines for treating specific features of the overlap CTDs are given in Table 86-6. Nearly all patients with CTDs experience Raynaud's phenomenon. Apart from advice on minimizing cold exposure, most patients should be tried on calcium channel blockers (e.g., nifedipine). The use of topical nitrates, endothelin antagonists (e.g., bosentan), phosphodiesterase-5

inhibitors (e.g., tadalafil), and prostaglandin analogues (e.g., iloprost) should be considered in severe refractory cases.¹⁰¹ Pulmonary hypertension is the main cause of death in MCTD, and patients should be evaluated at regular intervals for the development of this complication because early intervention is the key to effective management. Recent advances in the treatment of pulmonary hypertension have led to reduced morbidity and mortality.⁷⁷ Overall effective management requires anticoagulation and vasodilator therapy such as calcium channel blockers or prostacyclin analogues. Long-term treatment with intravenous epoprostenol or prostacyclin improves exercise capacity, hemodynamics, and survival in many patients,¹⁰² as does therapy with inhaled iloprost.¹⁰³ Evidence indicates that some patients respond to a regimen of intravenous cyclophosphamide and corticosteroids.¹⁰⁴ Bosentan, an oral endothelin-1 antagonist, has been reported to improve dyspnea and slow PAH progression in MCTD.¹⁰⁵

The management of overlap syndromes has not been the subject of controlled trials. Therefore management is based on an analysis of the clinical features and the application of management strategies used in the usual treatment of presenting features in terms of inflammatory arthritis, Raynaud's, inflammatory muscle disease, serositis, interstitial lung disease, pulmonary hypertension, and the gastrointestinal features of scleroderma. By definition, the clinical features of an overlap syndrome will be quite diverse and often change over time. Thus a constant reappraisal of management strategies is necessary at each patient visit.

Many of the problems causing morbidity in overlap syndromes tend to be intermittent and responsive to corticosteroids (e.g., aseptic meningitis, myositis, pleurisy, pericarditis, and myocarditis). On the other hand, nephrotic syndrome, Raynaud's phenomenon, deforming arthropathy, acrosclerosis, and peripheral neuropathies are usually steroid resistant. Many of the scleroderma-like gastrointestinal problems can be managed according to the usual practice in scleroderma such as management of renal crisis with angiotensin-converting enzyme inhibitors, Raynaud's phenomenon with calcium channel blockers, and gastrointestinal reflux disease with proton pump inhibitors.¹⁰¹ Fibrotic lung disease is notoriously resistant to corticosteroids and immunosuppressives; there is some evidence that a new class of drugs, the tyrosine kinase inhibitors (e.g., imatinib), may be effective in some patients.¹⁰⁶

In patients with steroid-resistant thrombocytopenia, refractory myositis, or hemolytic anemia, it is worth considering the use of intravenous gammaglobulin¹⁰⁷ or danazol.¹⁰⁸

Successful autologous peripheral blood stem cell transplantation has been reported in a patient with refractory myositis and MCTD.¹⁰⁹ Over the long term, concern usually mounts over the total corticosteroid burden and the possibility of inducing an iatrogenic steroid myopathy, nosocomial infection, aseptic necrosis of bone, or accelerated osteoporosis. Routine evaluation of bone mineral density is warranted to detect early presymptomatic osteoporosis and initiation of therapy with antiresorptive agents. Unless contraindicated, all patients should take supplementary calcium and vitamin D. In patients requiring long-term corticosteroids it would seem reasonable to use antimalarials¹¹⁰ or methotrexate¹¹¹ in an attempt to minimize the cumulative

Table 86-6 Guidelines for Managing Overlap Syndromes

Problems	Treatments
Fatigue, arthralgias, myalgias Arthritis Raynaud's phenomenon	NSAIDs, antimalarials, low-dose prednisone (<10 mg/day); trial use of modafinil NSAIDs, antimalarials, methotrexate. Consider TNF inhibition ^a Keep warm, avoid finger trauma, avoid β -blockers, stop smoking; dihydropyridine calcium channel blocker (e.g., nifedipine); α -sympatholytic (e.g., prazosin); consider endothelin receptor antagonist (e.g., bosentan) in recalcitrant cases
Acute-onset digital gangrene	Local chemical sympathectomy (infiltration of lidocaine at base of involved digit), anticoagulation, topical nitrates; consider hospitalization for intra-arterial prostacyclin; start endothelin receptor antagonist therapy
Pleurisy Pericarditis	NSAID or short course of prednisone (\approx 20 mg/day) NSAID or short course of prednisone (\approx 20 mg/day); tamponade will require percutaneous or surgical drainage
Aseptic meningitis Myositis	Discontinue NSAIDs ^b and give short course of high-dose prednisone, about 60 mg/day Acute onset, severe: prednisone 60-100 mg/day Chronic, low grade: prednisone, 10-30 mg/day ^c Consider methotrexate and/or IVIG in recalcitrant cases
Membranous glomerulonephropathy	Mild: no treatment required Progressive proteinuria: trial of ACE inhibitor; trial of low-dose aspirin combined with dipyridamole Severe: trial of prednisone 15-60 mg/day plus monthly pulse cyclophosphamide or daily chlorambucil
Nephrotic syndrome	Steroids alone are seldom effective. Low-dose aspirin combined with dipyridamole to prevent thrombotic complications; ACE inhibitor to reduce protein loss; trial of prednisone 15-60 mg/day plus monthly pulse cyclophosphamide or daily chlorambucil; dialysis or transplantation may be required
Scleroderma-like renal crisis Myocarditis Incomplete heart block Asymptomatic pulmonary hypertension	ACE inhibitor Trial of steroids and cyclophosphamide ^d ; avoid digoxin ^e Avoid chloroquine ^f Trial of steroids and cyclophosphamide, low-dose aspirin and ACE inhibitors; consider endothelin receptor antagonist (oral bosentan)
Symptomatic pulmonary hypertension	Intravenous prostacyclin, ACE inhibitors, anticoagulation, endothelin receptor antagonist (oral bosentan); trial of sildenafil; heart-lung transplantation
Vascular headache	Trial of propranolol and/or alternate-day aspirin, 350 mg Symptomatic use of a triptan (e.g., sumatriptin, eletriptan)
Autoimmune anemia/thrombocytopenia	High-dose steroids (\approx prednisone 80 mg/day) with taper dependent on clinical course. Consider danazol, IVIG, and immunosuppression in recalcitrant cases
Thrombotic thrombocytopenic purpura	Immediate infusion of fresh-frozen plasma; may require plasma exchange and transfusion of platelet-depleted RBCs; consider splenectomy in recalcitrant cases
Dysphagia	Mild: no treatment With reflux: proton pump inhibitor; consider Nissen fundoplication Severe: calcium channel antagonist, alone or in combination with an anticholinergic agent
Intestinal dysmotility	Prokinetic agents such as metoclopramide and erythromycin
Osteoporosis	Small bowel bacterial overgrowth: tetracycline, erythromycin Ca/Vit D supplements, estrogen replacement or raloxifene; bisphosphonates ^g ; nasal calcitonin; carboxyl-truncated PTH analogues such as hPTH-(1-34).
Heartburn/Dyspepsia	Raise head of bed, discontinue smoking, lose weight and avoid caffeine; H ₂ antagonists, H ⁺ proton pump blockers; trial of metoclopramide; consider <i>Helicobacter pylori</i> infection in recalcitrant cases
Trigeminal neuropathy	No effective therapy for numbness; trial of an antiepileptic (e.g., gabapentin) or tricyclic antidepressant (e.g., nortriptyline) for pain

^aHas been associated with flares in MCTD and SLE.

^bSulindac and ibuprofen have been associated with a hypersensitivity aseptic meningitis.

^cRemain alert for steroid myopathy, aseptic necrosis of bone, and accelerated osteoporosis.

^dCardiotoxic at high doses.

^ePredisposes to ventricular arrhythmias.

^fPredisposes to complete heart block.

^gCannot be used if esophagus is more than mildly involved.

ACE, angiotensin-converting enzyme; IVIG, intravenous immunoglobulin; NSAID, nonsteroidal anti-inflammatory drug; PTH, parathyroid hormone; RBC, red blood cell; TNF, tumor necrosis factor.

steroid burden. Antimalarials should be used with caution in overlap patients with a fascicular or bundle branch block due to the risk of causing a complete heart block¹¹² or an idiosyncratic hepatitis.¹¹³ Digitalis is relatively contraindicated in patients with myocarditis due to the risk of inducing ventricular arrhythmias. As in SLE, the tumor necrosis factor inhibitor etanercept has been reported to exacerbate MCTD.¹¹⁴ Rituximab has been beneficial in some patients

with severe refractory antisynthetase syndrome.¹¹⁵ Patients with severe hand deformities may be helped by soft tissue release operations and selected joint fusions.

The management of pregnancy presents several special problems in patients with overlap CTDs. Doria and colleagues¹¹⁶ have provided the following general advice:

1. Patients should be correctly informed about the risk of becoming pregnant.

2. Pregnancies should be planned when the disease is in remission because it increases the probability of successful maternal and fetal outcome.
3. Patients should be regularly monitored during gestation and postpartum by a multidisciplinary team including a rheumatologist, an obstetrician, and a neonatologist.
4. In the case of disease relapse an adequate treatment, even aggressive if necessary, should be recommended because active disease can be more detrimental for a fetus than drugs.

There is often a tendency to assume that all patients with overlap CTDs should be on long-term corticosteroids; this mistake is compounded by the assumption that all medical problems in these patients are related to their underlying overlap CTDs. For instance, apparent flares of discomfort and pain in overlap CTDs may be due to myofascial pain syndrome or fibromyalgia and are thus unresponsive to corticosteroids. Likewise, the feeling of malaise and easy fatigability may be related to a reactive depression or the fact that the patient has become deconditioned. Premature atherosclerosis is now well recognized as a cause of increased morbidity and mortality in AICTDs,¹¹⁷ and all patients with overlap syndromes need ongoing evaluation for risk factors and appropriate advice and therapy for hypertension and hyperlipidemia. The management of patients with overlap CTDs requires continuing reassessment of an ever-changing pattern of clinical problems and a constant alertness to the iatrogenic disease. As with any disease of unknown etiology, effective management of patients with the overlap CTDs presents a constant and ever-evolving challenge.

OUTCOME

The prognosis for overlap syndromes is often better than the classic AICTDs. For instance, Troyanov reported on the follow-up of 100 patients with idiopathic inflammatory myopathy. It was found that the long-term course after treatment with prednisone, with a dose/duration that initially resulted in good symptomatic improvement, was strikingly different; all PM patients (100%) and most DM patients (92%) progressed to chronic myositis, whereas only 58% of overlap patients developed persistent muscle disease.⁴ The tendency for overlap patients to develop chronic disease was more common in those with antisynthetase and nucleoporin antibodies and less with antibodies to U1-RNP, PM/Scl, or Ku. Patients with three or four U1 snRNP antibodies (i.e., anti-70 kD, anti-A, anti-C, and anti-U1 snRNA) tended to have minimal renal disease compared with patients with just one or two reactivities.¹¹⁸ Antibodies to 155-kD and 140-kD proteins in myositis are a risk factor for the development of cancer.¹¹⁹ There is unequivocal evidence that patients with high-titer U1-RNP antibodies have a low prevalence of serious renal disease and life-threatening neurologic problems; in this sense MCTD can be favorably compared with classic SLE. However, not all patients with MCTD have a favorable prognosis and death may occur from progressive pulmonary hypertension and its cardiac sequelae. A 38-year follow-up of 47 MCTD patients at the University of Missouri reported a favorable course in 62% and continuing active disease in 38%. Eleven (23%) patients had a fatal outcome related to

pulmonary hypertension in nine patients and two deaths unrelated to MCTD.¹²⁰ It is evident that the course of overlap syndromes is unpredictable; many patients do follow a relatively benign course, but it is major organ involvement that ultimately dictates the morbidity and mortality of the disease.

Classification and Epidemiology of Systemic Vasculitis

JOHN H. STONE

KEY POINTS

Vasculitis is a heterogeneous group of disorders linked by the primary finding of inflammation within blood vessel walls. At least 20 forms of systemic vasculitis are recognized currently.

Vasculitides are classified first by the size of blood vessel involved—small (capillaries and postcapillary venules), medium (muscular arteries and arterioles), or large (the aorta and its major branches).

Additional considerations in classification include patient demographics, organ tropism, presence or absence of granulomatous inflammation, participation (or not) of immune complexes, finding of autoantibodies, and detection of infections associated with some vasculitides.

Different forms of vasculitis have widely divergent profiles with regard to age, gender, and ethnicity.

Associations between genes and vasculitis have been recognized increasingly in recent years. There also has been progress in the area of gene-environment interactions.

CLASSIFICATION

Few disorders in medicine are more challenging in diagnosis and treatment than the systemic vasculitides. These heterogeneous disorders are linked by the common finding of destructive inflammation within the walls of blood vessels. Current classification schemes recognize approximately 20 primary forms of vasculitis and several major categories of secondary vasculitis (e.g., other rheumatologic diseases, malignancy, infection) (Table 87-1). Over the past half century, numerous comprehensive classification schemes have been attempted.¹ No attempt has been entirely satisfactory because understanding of these conditions continues to evolve. All vasculitis classification schemes are works in progress, susceptible to change as new information emerges.

Current classification schemes are understood best in light of their nosologic predecessors. The first “modern” case of systemic vasculitis was recognized in the 1860s by Kussmaul and Maier.² That case, which involved medium-sized, muscular arteries, has served as the reference point for

classifying many subsequently recognized forms of vasculitis. Because of the importance of that first report in the understanding and classification of vasculitis, the case is described in detail here.

First Modern Case: “Periarteritis Nodosa”

In 1866 Kussmaul and Maier reported the case of a 27-year-old tailor who died during a month-long hospital stay.^{2,3} On presentation, the patient was strong enough to climb two flights of stairs to the clinic but “afterward felt so weak that he immediately had to go to bed.” He complained of numbness on the volar aspect of his thumb and the two neighboring fingers on the right hand. Over the ensuing days, “the general weakness increased so rapidly that he was unable to leave the bed, [and] the feeling of numbness also appeared in the left hand.” Muscle paralysis progressed quickly: “Before our eyes, a young man developed a general paralysis of the voluntary muscles ... [He] had to be fed by attendants, and within a few weeks was robbed of the use of most of his muscles.”^{2,3}

The patient’s weakness, caused by vasculitic neuropathy (mononeuritis multiplex), was accompanied by tachycardia, abdominal pains, and the appearance of cutaneous nodules over his trunk. His death was described as follows: “He was scarcely able to speak, lay with persistent severe abdominal and muscle pains, opisthotonically stretched, whimpering, and begged the doctors not to leave him ... Death occurred ... at 2 o’clock in the morning.” At autopsy, grossly visible nodules were present along the patient’s medium-sized arteries. Kussmaul and Maier² suggested the name “periarteritis nodosa” for this disease because of the apparent localization of inflammation to the perivascular sheaths and outer layers of the arterial walls, leading to nodular thickening of the vessels. The name was later revised to polyarteritis nodosa (PAN), to reflect the widespread arterial involvement of this disease and the fact that inflammation in PAN extends through the entire thickness of the vessel wall.^{4,5}

Polyarteritis Nodosa as a Reference Point

In addition to its status as the first form of vasculitis recognized, several features of PAN make it a logical reference

Table 87-1 Classification Scheme of Vasculitides According to Size of Predominant Blood Vessels Involved

Primary Vasculitides
<i>Predominantly Large Vessel Vasculitides</i>
Takayasu's arteritis
Giant cell arteritis (temporal arteritis)
Cogan's syndrome
Behçet's disease*
<i>Predominantly Medium Vessel Vasculitides</i>
Polyarteritis nodosa
Cutaneous polyarteritis nodosa
Buerger's disease
Kawasaki disease
Primary angiitis of the central nervous system
<i>Predominantly Small Vessel Vasculitides</i>
Immune complex mediated
Goodpasture's disease (anti-glomerular basement membrane disease) [†]
Cutaneous leukocytoclastic angiitis ("hypersensitivity vasculitis")
Henoch-Schönlein purpura
Hypocomplementemic urticarial vasculitis
Essential cryoglobulinemia [‡]
Erythema elevatum diutinum
ANCA-associated disorders [§]
Granulomatosis with polyangiitis (formerly Wegener's granulomatosis) [‡]
Microscopic polyangiitis [‡]
Churg-Strauss syndrome [‡]
Renal-limited vasculitis
Secondary Forms of Vasculitis
<i>Miscellaneous Small Vessel Vasculitides</i>
Connective tissue disorders [‡] (rheumatoid vasculitis, lupus erythematosus, Sjögren's syndrome, inflammatory myopathies)
Inflammatory bowel disease
Paraneoplastic
Infection
Drug-induced vasculitis: ANCA-associated, other

*May involve small, medium, and large blood vessels.

[†]Immune complexes formed in situ, in contrast to other forms of immune complex-mediated vasculitis.

[‡]Frequent overlap of small and medium blood vessel involvement.

[§]Not all forms of these disorders are always associated with ANCA.

ANCA, antineutrophil cytoplasmic antibody.

point for the classification of inflammatory vascular disease. Other forms of vasculitis can usually be differentiated from PAN through their contrasts to one or more of the following PAN characteristics:

- The general confinement of the disease to medium-sized vessels* as opposed to capillaries and postcapillary venules (small vessels) and the aorta and its major branches (large vessels)
- The exclusive involvement of arteries, with sparing of veins
- The tendency to form microaneurysms
- The absence of lung involvement
- The lack of granulomatous inflammation
- The absence of associated autoantibodies (e.g., antineutrophil cytoplasmic antibodies [ANCA],

anti-glomerular basement membrane [anti-GBM] antibodies, or rheumatoid factor)

- The association of some cases with hepatitis B virus (HBV) infection

Classification by Vessel Size

Because the etiologies of most forms of vasculitis are unknown, the most valid basis for classifying the vasculitides is the size of the predominant blood vessels involved. Under such classification schemes, the vasculitides are categorized initially by whether the vessels affected are large, medium, or small (see Table 87-1 and Figure 87-1). "Large" generally denotes the aorta and its major branches (and the corresponding vessels in the venous circulation in some forms of vasculitis, e.g., Behçet's disease). "Medium" refers to vessels that are smaller than the major aortic branches yet still large enough to contain four elements: (1) an intima, (2) a continuous internal elastic lamina, (3) a muscular media, and (4) an adventitia. In clinical terms, medium vessel vasculitis (see Table 87-1) is generally macrovascular (i.e., involves vessels large enough to be observed in gross pathologic specimens or visualized by angiography). "Small vessel" vasculitis, which incorporates all vessels below macroscopic disease, includes capillaries, postcapillary venules, and arterioles. Such vessels all are typically less than 500 μ m in outer diameter. Because glomeruli may be viewed simply as differentiated capillaries, forms of vasculitis that cause glomerulonephritis are considered to be small vessel vasculitides. Table 87-2 presents the typical clinical manifestations associated with small, medium, and large vessel vasculitides.

All discussions of vasculitis classification schemes involving vessel size must acknowledge the frequent occurrence of overlap. Although PAN primarily involves medium-sized arteries, palpable purpura—a manifestation of small vessel disease—is observed in some cases. Despite the possibility of vessel size overlap within individual cases, the categorization of a patient's vasculitis as primarily large, medium, or small vessel in nature remains enormously useful in focusing the differential diagnosis and initiating plans for treatment.

Additional Considerations in Classification

Many other considerations are important in the classification of vasculitis (Table 87-3): (1) the patient's demographic profile (see Epidemiology section), (2) the disease's tropism for particular organs, (3) the presence or absence of granulomatous inflammation, (4) the participation of immune complexes in disease pathophysiology, (5) the finding of characteristic autoantibodies in the patients' serum (e.g., ANCA, anti-GBM antibodies, or rheumatoid factor), and (6) the detection of certain infections known to cause specific forms of vasculitis.

The organ tropisms of these disorders are illustrated by the following examples. Granulomatosis with polyangiitis (formerly Wegener's granulomatosis) and herein abbreviated GPA, classically involves the kidneys, upper airways, and lungs. In contrast, Henoch-Schönlein purpura often affects the kidneys, but never the nose or sinuses and almost never the lungs. In contrast to both of these forms of

*The fact of vessel size overlap in vasculitis syndromes is acknowledged and discussed subsequently.

Figure 87-1 Classification by blood vessel size. ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane.

vasculitis, Cogan's syndrome is defined by the simultaneous occurrence of ocular inflammation (most often interstitial keratitis) and sensorineural hearing loss (and, in 10% of cases, a large vessel vasculitis). The histopathologic findings in these three disorders are equally distinctive, ranging from granulomatous inflammation of small to medium vessels (GPA), to IgA deposition in small vessels (Henoch-Schönlein purpura), to large vessel vasculitis centered on the adventitia (Cogan's syndrome).

The granulomatous features of some forms of vasculitis resemble chronic infections (e.g., infections caused by fungi or mycobacteria) or the inflammation induced by the presence of a foreign body. Granulomatous inflammation is more likely to be found in some organs (e.g., the lung) than in others (e.g., the kidney or skin). Some patients without evidence of granulomatous inflammation at early points in their courses later exhibit such features as their diseases unfold. Patients initially diagnosed with cutaneous leukocytoclastic angiitis or microscopic polyangiitis may be reclassified as having GPA if disease manifestations appear in new organs and granulomatous inflammation is found on biopsy

specimens. Table 87-4 presents forms of vasculitis commonly associated with granulomatous inflammation.

Immune complexes are essential to the pathophysiology of some small and medium vessel vasculitides. Immune complex-mediated tissue injury does not produce a single clinical syndrome, but rather applies to many forms of vasculitis and overlaps with injuries caused by other immune mechanisms. Anti-GBM disease (Goodpasture's disease) is a unique form of immune complex disease in which the immune complexes form *in situ* rather than in the circulation.⁶ Complexes of IgA1 are found in Henoch-Schönlein purpura. Immune complexes comprising IgG, IgM, complement components, and the hepatitis C virion characterize most cases of mixed cryoglobulinemia. HBV surface antigen/antibody complexes are present in the circulation and involved tissues of patients with HBV-associated PAN. Rheumatoid factor and complement proteins are found within organs involved by rheumatoid vasculitis.

In contrast, other small and medium vessel vasculitides such as GPA, microscopic polyangiitis, and Churg-Strauss syndrome are disorders associated with "pauci-immune"

Table 87-2 Typical Clinical Manifestations of Large, Medium, and Small Vessel Involvement by Vasculitis

Large	Medium	Small
Limb claudication	Cutaneous nodules	Purpura
Asymmetric blood pressures	Ulcers	Vesiculobullous lesions
Absence of pulses	Livedo reticularis	Urticaria
Bruits	Digital gangrene	Glomerulonephritis
Aortic dilation	Mononeuritis multiplex	Alveolar hemorrhage
Renovascular hypertension	Microaneurysms	Cutaneous extravascular necrotizing granulomas
	Renovascular hypertension	Splinter hemorrhages
		Uveitis/episcleritis/scleritis

Constitutional symptoms: fever, weight loss, malaise, arthralgias/arthritis (common to vasculitides of all vessel sizes)

inflammation. “Pauci-immune” refers not to a lack of immunologic involvement in these disorders, but rather to the absence of significant immunoreactant deposition (immunoglobulin or complement) within diseased tissues. Many (but not all) patients with pauci-immune forms of vasculitis have ANCAs in their serum. Three decades before the description of ANCAs, Godman and Churg⁷ observed pathologic links between these three entities, noting that the disorders “group themselves into a compass, [ranging from] necrotizing and granulomatous processes with angiitis, through mixed forms, to vasculitis without granulomata.”

ANCAs (see Chapter 89) are directed against antigens that reside within the primary granules of neutrophils and monocytes.⁸ Two types of ANCAs seem to be relevant to vasculitis: (1) ANCAs directed against proteinase-3 (PR3), a serine protease found within the primary granules of neutrophils and monocytes; and (2) ANCAs directed against myeloperoxidase and another serine protease found within the same granules. Although rigorous serologic assays for these antibodies are helpful in diagnosis, evidence for a primary etiologic role of these antibodies in human forms of pauci-immune vasculitis is still lacking. In contrast, anti-GBM antibodies have been proven to play a major role in the pathogenesis of Goodpasture's disease.⁹ In RA, systemic rheumatoid vasculitis occurs only in patients who are rheumatoid factor positive. Rheumatoid factor is believed to play an essential role in the immune complex nature of that disease complication. Finally, although the causes of most forms of vasculitis are unknown, several infections have

been linked definitively with specific forms of these diseases (e.g., HBV with some cases of PAN, hepatitis C with type II mixed cryoglobulinemia).

Historical Attempts at Classification and Nomenclature

For decades after this initial description of vasculitis, most forms of systemic inflammatory vascular disease were termed *periarteritis nodosa*. In the 1900s, two major factors led to the recognition of new forms of vasculitis: (1) the use of microscopy in the evaluation of pathologic specimens became routine, and (2) horse serum and sulfonamides came to be employed in the treatment of many medical conditions. These new therapies frequently induced small vessel vasculitides on the basis of serum sickness or “hypersensitivity” phenomena, which were observed readily through the microscope. In some cases, the histopathologic findings of hypersensitivity reactions (e.g., serum sickness) were confused with *periarteritis nodosa*. The gradual recognition that these syndromes represented departures from PAN spurred interest in the first classification scheme for necrotizing angiitis.

In 1952 Zeek¹⁰ identified five major categories of necrotizing angiitis. The Zeek classification included (1) hypersensitivity angiitis, (2) allergic granulomatous angiitis (Churg-Strauss syndrome), (3) rheumatic arteritis (vasculitis associated with fulminant rheumatic fever), (4) *periarteritis nodosa*, and (5) temporal arteritis. This classification scheme omitted several forms of systemic vasculitis that were known but not yet described in the English medical literature (e.g., GPA, Takayasu's arteritis).

Sources of Confusion in Classification

Two forms of vasculitis, now termed *microscopic polyangiitis* and *cutaneous leukocytoclastic angiitis*, have been consistent sources of confusion in vasculitis nosology. In the current understanding of systemic vasculitides, these two conditions are separate entities. Microscopic polyangiitis affects capillaries, veins, and arteries (in contrast to PAN) and is recognized to be a disorder associated with ANCAs in approximately 70% of cases.¹¹ In 1923 Wohlwill¹² observed unequivocal evidence of small vessel involvement in cases of vasculitis that he still considered part of the spectrum of “*periarteritis nodosa*.” Davson and colleagues¹³ remarked on two forms of “*periarteritis nodosa*” with differential effects on the kidney—one with a predilection for medium-sized, muscular arteries and the other with a predilection for small vessels including glomerulonephritis. Davson and colleagues¹³ termed this latter form *microscopic periarteritis nodosa*. Swayed by human and animal models of hypersensitivity that showed small vessel disease involving the kidneys, lungs, and other organs,^{14,15} Zeek chose to group microscopic *periarteritis nodosa* under the heading of *hypersensitivity vasculitis*.¹⁰

Over the next several decades, hypersensitivity vasculitis came to refer to an immune complex-mediated small vasculitis of the skin that spared internal organs and often followed drug exposures.¹⁶ The Chapel Hill Consensus Conference (CHCC)¹⁷ (see later) recommended eliminating the term *hypersensitivity* altogether because evidence for

†Giant cells occur within inflammatory thrombi (and are diagnostic of Buerger's disease) but do not occur within the blood vessel wall.

hypersensitivity is lacking in many cases. Participants in the CHCC preferred the term *cutaneous leukocytoclastic angiitis* because of the disorder's typical confinement to the skin and the usual predominant cell type—the neutrophil. Although cutaneous leukocytoclastic angiitis can mimic the skin features of microscopic polyangiitis, cutaneous leukocytoclastic angiitis does not involve the kidneys, lungs, peripheral nerves, and other internal organs and is not associated with ANCA.

In 1990 the American College of Rheumatology (ACR) performed a study designed to establish criteria for the classification of vasculitis, through the identification of features that distinguished one form of vasculitis from others.^{18,19} An important caveat: This study was *not* designed to establish criteria for diagnosis, but rather to facilitate research by permitting the inclusion of similar types of patients in studies. Patients with giant cell arteritis, Takayasu's arteritis, PAN, GPA, Churg-Strauss syndrome, Henoch-Schönlein purpura, and hypersensitivity vasculitis were included in this study.^{16,20-25} The findings of the ACR study remain useful for the purposes of the study's original intention—the insurance of uniform inclusion criteria for patients in research studies. The passage of time and the development of new insights have shown the need for updates, however. First, because the study was performed before the days of reliable and widely available assays for ANCA, ANCA positivity was not considered as a possible classification criterion. Second, the ACR classification criteria study did not include microscopic polyangiitis as a separate disease, but rather lumped such patients under the heading of PAN.²² Third, the study did not define classification criteria for such rarer forms of vasculitis as Cogan's syndrome and Behçet's syndrome. As noted subsequently, Behçet's syndrome is rare in North America but not in countries bordering the Old Silk Route. Classification criteria for this disease have been defined.²⁶

In 1994 the CHCC reviewed the nomenclature of systemic vasculitides. Formal diagnostic criteria were not attempted, but definitions were created for 10 forms of vasculitis (in addition to the 7 forms of vasculitis included in the ACR study, microscopic polyangiitis, Kawasaki disease, and "essential" cryoglobulinemic vasculitis were defined). The CHCC emphasized the important role that ANCA play in the diagnosis of several forms of vasculitis and carefully distinguished microscopic polyangiitis from classic PAN. The conference defined classic PAN as necrotizing inflammation of medium-sized or small arteries without

glomerulonephritis.¹⁷ Microscopic polyangiitis was defined as a necrotizing vasculitis with few or no immune deposits that (1) affects small blood vessels (capillaries, venules, or arterioles), (2) often includes glomerulonephritis and pulmonary capillaritis, and (3) is often associated with either myeloperoxidase ANCA or PR-3 ANCA.

The classification of vasculitis continues to evolve. In the years since the CHCC, it has become clear that hepatitis C plays a major role in 90% of cases that formerly were termed *essential mixed cryoglobulinemia*. Some cases of this syndrome are not associated with hepatitis C infections, however, and probably have some other infectious etiology. Similarly, with the availability of the HBV vaccine, increasingly fewer cases of PAN are associated with this infection. Most PAN cases have no known cause. As emphasized by Churg,²⁷ cases of PAN currently termed *idiopathic* do not represent a single entity but almost certainly include several different disorders. Some of these, as indicated by low serum complement levels and measurable immune complexes in the blood, are mediated by immune complex deposition. Others seem to be independent of this mechanism. Finally, although *cutaneous leukocytoclastic angiitis* may be preferable to *hypersensitivity vasculitis* in describing small vessel vasculitis confined to the skin, the term fails to acknowledge the few cases in which lymphocytic infiltrates predominate and the nonspecific term "lymphocytic vasculitis" is used.

EPIDEMIOLOGY

Accurate definition of the epidemiology of vasculitis confronts several challenges, as follows: (1) the uncommon nature of many forms of vasculitis; (2) the frequent difficulties in making the correct diagnosis of vasculitis (and in distinguishing one form of vasculitis from another); (3) the fact that the etiologies of most types of vasculitis remain unknown; and (4) historical uncertainty with regard to the classification of these conditions. Nevertheless, in recent years, the epidemiology of some forms of vasculitis has been defined with reasonable precision. Table 87-5 presents the major epidemiologic features of several forms of systemic vasculitis.

Geography

The epidemiologic features of systemic vasculitis vary tremendously by geography. This variation may reflect

Table 87-5 Epidemiology of Selected Forms of Vasculitis

Disease	Incidence		Age/Gender/Ethnic Predispositions
	United States	Elsewhere	
Giant cell arteritis	240/1 million	240/1 million (Scandinavia)	Age > 50, mean age 72; females 3:1/Northern European ancestry
Takayasu's arteritis	3/1 million	200-300/1 million (India)	Age <40; females 9:1/Asian
Behçet's disease	3/1 million	3000/1 million (Turkey)	Silk Route countries
Polyarteritis nodosa	7/1 million	7/1 million (Spain)	Slight male predominance
Kawasaki disease	100/1 million*	900/1 million (Japan)	Children of Asian ancestry
Granulomatosis with polyangiitis	4/1 million	8.5/1 million (United Kingdom)	Whites >> blacks
Henoch-Schönlein purpura	In children: 135-180/1 million; in adults: 13/1 million		Only 10% of cases occur in adults

*Among children younger than 5 years of age.

From Gonzalez-Gay MA, Garcia-Porrúa C: Epidemiology of the vasculitides, *Rheum Dis Clin North Am* 27:729-750, 2001.

genetics, differences in environmental exposures dictated by continent and latitude, and the prevalence of other disease risk factors. Although Behçet's syndrome is rare in North Americans (affecting only approximately 1 in 300,000), the condition is perhaps several hundred times more common among inhabitants of countries that border the ancient Silk Route.^{26,28} Similarly, although Takayasu's arteritis is rare in the United States—on the order of 3 new cases per 1 million people per year—the disease is reportedly the most common cause of renal artery stenosis in India, where the incidence may be 200 to 300 per million per year. Several studies indicate that the prevalence of giant cell arteritis in Olmsted County, Minnesota; is similar to that of Scandinavian countries, with an annual incidence rate of approximately 240 cases for every 1 million individuals older than age 50 years.²⁹ The similar prevalence calculations across these countries probably reflect shared genetic risk factors for this condition because many of the current inhabitants of Olmsted County are descended from Scandinavia and northern Europe. On the basis of 2010 U.S. Census data, the prevalence of giant cell arteritis in the United States is on the order of 200,000 cases.

Age, Gender, and Ethnicity

Age is an important consideration in the epidemiology of vasculitis. Of patients with Kawasaki disease, 80% are younger than age 5 years.³⁰ In contrast, giant cell arteritis virtually never occurs in patients younger than age 50, and the mean age of patients with that disease is 72. Age also may affect disease severity and outcome. In Henoch-Schönlein purpura, most cases in children (who comprise 90% of all cases) have self-limited courses, resolving within several weeks. In adults, Henoch-Schönlein purpura may have a higher likelihood of chronicity and a greater likelihood of a poor renal outcome.³¹

The distribution of gender varies across many forms of vasculitis. Buerger's disease is the only form of vasculitis with a striking male predominance. The predilection of this disease for men may be explained by the greater prevalence of smoking among men in most societies. In contrast, Takayasu's arteritis has an overwhelming tendency to occur in women (a 9:1 female-to-male ratio), a fact that presently has no explanation. Pauci-immune forms of vasculitis such as GPA occur in men and women with approximately equal frequencies, but there is some evidence for a female predominance in patients with the limited form of the disease and a male predominance among patients with severe GPA.³²

For some forms of vasculitis, there are striking variations in tendencies to affect specific ethnic groups. Giant cell arteritis and GPA occur with an overwhelming predominance in whites.³³⁻³⁵ Takayasu's arteritis and Kawasaki disease have higher incidences in patients of Asian ancestry.

Genes

Although genetic risk factors are undoubtedly important in the susceptibility to some forms of vasculitis, familial cases are rare (with the exception of giant cell arteritis; see later). The rarity of familial cases in vasculitis indicates that the genetics of these disorders are polygenic and complex. The

strongest link between any single gene and vasculitis is the association of HLA-B51 with Behçet's disease. In Behçet's disease, 80% of Asian patients have the *HLA-B51* gene.²⁸ The prevalence of *HLA-B51* is significantly higher among patients with Behçet's disease in Japan than among nondisease controls (55% vs. < 15%). Among the sporadic cases of Behçet's disease involving white patients in the United States, however, *HLA-B51* occurs in less than 15% of cases. In addition to increasing the risk of disease susceptibility in some patients, *HLA-B51* increases disease severity. Patients with this gene are more likely to have posterior uveitis, central nervous system involvement, or other severe manifestations.

Reports of familial aggregation in giant cell arteritis are common. Genetic studies have indicated roles for HLA class II alleles such as *HLA-DRB1*0401* and *HLA-DRB1*0101*, albeit the specific associations have varied from study to study.^{36,37} Other work indicates that certain tumor necrosis factor microsatellite polymorphisms may contribute to disease susceptibility.³⁸

The greatest progress in understanding the relationship of genetics to systemic vasculitis has come in the area of rheumatoid vasculitis. The contribution of the "shared epitope" found on class II human leukocyte antigen (HLA) molecules (DR4) to the development of rheumatoid arthritis (RA) has been appreciated for 2 decades.³⁹ Possession of the shared epitope is now known to substantially increase the risk of extraarticular manifestations in RA including vasculitis, at least in Northern European populations. A gene dosage effect for extra-articular RA with severe organ manifestations has been noted; patients with two copies of shared epitope alleles have a substantially higher risk of extra-articular disease manifestations, many of which are mediated by vasculitis.⁴⁰ One study reported an association between rheumatoid vasculitis and 0401/0404.⁴¹

In a case-control study of patients with severe extra-articular RA compared with RA patients without extra-articular disease manifestations, the presence of two *HLA-DRB1*04* alleles encoding the shared epitope was associated with extra-articular RA (odds ratio [OR], 1.79; 95% confidence interval [CI], 1.04 to 3.08) and rheumatoid vasculitis (OR, 2.44; 95% CI, 1.22 to 4.89).⁴² In a meta-analysis of *HLA-DRB1* genotyping studies of patients with rheumatoid vasculitis,⁴³ rheumatoid vasculitis was found to be associated with the genotypes 0401/0401, 0401/0404, and 0401/0101.

An association between rheumatoid vasculitis and class I HLA molecules has also been reported. An analysis of 159 patients with severe extra-articular RA (46 of whom had vasculitis) and 178 RA patients without extra-articular disease reported a strong association between the *HLA-C3* allele and vasculitis.⁴⁴ Among vasculitis patients, the allele frequency of *HLA-C3* was 0.411 compared with 0.199 in RA patients without extra-articular disease ($P < .001$). The odds ratio for vasculitis in patients with *HLA-C3* was 4.15 (95% CI, 2.14 to 8.08).

The association between *HLA-C3* and vasculitis was not due to linkage disequilibrium with *HLA-DRB1*, suggesting that these two genetic risk factors operate through different pathways. *HLA-C3* was a strong predictor of vasculitis in patients lacking *HLA-DRB1*04* shared epitope alleles, suggesting that *HLA-C* and *HLA-DR* genes influence the RA

disease process through different pathways. Linkage disequilibrium with other genes in the major histocompatibility complex (MHC) could not be excluded in this study, however.

In GPA, the allele frequency of a functional polymorphism, 620W, in the intracellular tyrosine phosphatase gene *PTPN22* was found to be increased significantly among ANCA-positive patients compared with healthy controls.⁴⁵ Analyses of families with multiple autoimmune disorders have identified this allele as a risk factor for type 1 diabetes, seropositive RA, systemic lupus erythematosus, and autoimmune thyroid disease. In GPA, the allelic association was particularly strong among patients with generalized disease (i.e., vasculitis involving the kidney, lung, eye, and peripheral nervous system).

Study of the relationships between genes and systemic vasculitis is in its infancy. Substantial progress can be anticipated in this area in the future.

Environment

Several environmental and occupational exposures have been linked to the development of vasculitis. Medications and certain infections have well-known associations with vasculitides. As examples, antibiotics such as the penicillins and cephalosporins are common causes of hypersensitivity vasculitis (see Chapter 91), and virtually any medication can trigger this syndrome. Hepatitis B and C have well-recognized links to polyarteritis nodosa and mixed cryoglobulinemia, respectively. Moreover, both medications and infections can serve as triggers for Henoch-Schönlein purpura.

The strongest environmental exposure, now linked convincingly to Buerger's disease and to rheumatoid vasculitis, is cigarette smoking. Buerger's disease does not occur in the absence of cigarette smoking. The relationship between smoking and Buerger's disease is usually one of primary exposure (usually heavy), but cases related to second-hand smoke have been alleged.

In a case-control study of patients with recent-onset RA, the interactions among smoking, shared epitope genes, and antibodies to citrullinated proteins were studied.⁴⁶ A dose-dependent relationship between smoking and the occurrence of anti-cyclic citrullinated peptide antibodies was found. The presence of shared epitope genes was a risk factor for RA only among patients who were positive for anticyclic citrullinated protein. A major gene-environment interaction between smoking and HLA-DR SE genes was evident in the large subgroup of patients who possessed anticyclic citrullinated protein antibodies: The combination of smoking history and double copies of shared epitope alleles increased the risk of RA 21-fold. Smoking may trigger RA-specific immune reactions to citrullinated proteins in the context of shared epitope genes.

Associations have been reported, but not confirmed, between exposure to inhaled silica dust and some types of pauci-immune vasculitis.⁴⁷ Precise definitions of the relationships between exposures and vasculitis are complicated by difficulties in obtaining reliable measurements of the levels of such exposures, the likelihood of recall bias among patients who are diagnosed with vasculitis, and the choice of appropriate control groups.

Finally, estimates of disease prevalence in vasculitis may be subject to revision because of changing disease definitions. In the ACR classification criteria study, manifestations of small and medium vessel involvement were included in the criteria for PAN.²² Four years later, the CHCC defined PAN as a form of arterial inflammation limited to medium-sized vessels, sparing capillaries, arterioles, and venules.¹⁷ Under this definition, classic PAN is believed to be a rare condition. Applying the CHCC definition retrospectively, not a single case of classic PAN was reported over a 6-year period in the region of the Norwich Health Authority (United Kingdom), an area that included a population of more than 400,000.^{48,49}

The epidemiologic differences among individual types of vasculitis raise compelling questions about the etiologies of these diseases. Ultimately, better insights into the pathogenesis of these conditions should explain these epidemiologic differences and facilitate the development of more refined classification schemes.

KEY POINTS

Giant cell arteritis affects adults older than 50 years.

The most common manifestations of giant cell arteritis are constitutional symptoms, headache, jaw claudication, and visual symptoms; almost all untreated patients have an elevated erythrocyte sedimentation rate.

The diagnosis of giant cell arteritis is usually confirmed by temporal artery biopsy.

Early treatment of giant cell arteritis can prevent blindness.

Polymyalgia rheumatica can occur by itself or with giant cell arteritis.

Polymyalgia rheumatica responds to prednisone 10 to 20 mg/day, whereas giant cell arteritis requires an initial dose of prednisone of approximately 60 mg/day.

Takayasu's arteritis most frequently affects the aorta and its major branches in young women.

Giant cell arteritis (GCA) and polymyalgia rheumatica (PMR) are discussed together because they affect similar epidemiologic subsets of patients and often occur together in the same individual. Although GCA is a disease of older people and Takayasu's arteritis is a disease of younger people, their shared predilection for causing vasculitis of large arteries and their nearly identical histopathologic changes prompt their inclusion in the same chapter.

GIANT CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

American College of Rheumatology Criteria

Classification criteria for the diagnosis of GCA have been proposed by the American College of Rheumatology (ACR) (Table 88-1).¹ Three classification schemes have been proposed for PMR (Table 88-2).^{2,3,3a} The provisional criteria for 2012 were developed in part to incorporate information from ultrasound evaluation.

Definitions

Giant Cell Arteritis

GCA is the most common form of systemic vasculitis in adults.⁴ The disease affects primarily the extracranial branches of the carotid artery in patients older than 50 years. The most feared complication of GCA is irreversible loss of vision. Because the cause of GCA is unknown,

Giant Cell Arteritis, Polymyalgia Rheumatica, and Takayasu's Arteritis

DAVID B. HELLMANN

various names—including temporal arteritis, cranial arteritis, and granulomatous arteritis—have been used to highlight different salient features.⁵ All the names for this disease have both merits and shortcomings. The designation *temporal arteritis* or *cranial arteritis*, for example, conveys how frequently the temporal arteries or other cranial arteries are involved but fails to capture GCA's more widespread nature. Although *granulomatous arteritis* and GCA pay homage to an important pathologic finding, this focus is undeserved because giant cells are absent in about half the cases and may be present in other forms of vasculitis. With no perfect name available, this chapter bows to convention and refers to this disease as GCA.

Polymyalgia Rheumatica

Polymyalgia rheumatica, a term suggested by Barber, is a syndrome characterized by aching in the proximal portions of the extremities and torso. Because there are no specific diagnostic tests or pathologic findings, PMR is defined by its clinical features. The features included in most definitions of PMR are as follows (1) aching and morning stiffness lasting half an hour or longer in the shoulder, hip girdle, neck, or some combination; (2) duration of these symptoms for 1 month or longer; (3) age older than 50 years; and (4) laboratory evidence of systemic inflammation such as an elevated erythrocyte sedimentation rate (ESR).² Some definitions also include a rapid response to small doses of glucocorticoids such as prednisone 10 mg/day.⁶ The presence of another specific disease other than GCA such as rheumatoid arthritis (RA), chronic infection, polymyositis, or malignancy excludes the diagnosis of PMR.

Epidemiology

The incidence of GCA varies widely in different populations, from less than 0.1 per 100,000 to 77 per 100,000 persons aged 50 years and older.^{4,7-11} The greatest risk factor for developing GCA is aging; the disease almost never occurs before age 50, and its incidence rises steadily thereafter. The average age at diagnosis has risen over the past half century, from 74.7 years in the 1950s to 79.2 years now.¹² Nationality, geography, and race are also important, with the highest incidence figures found in Scandinavians and in Americans of Scandinavian descent. The lowest incidence of GCA is reported in Japanese, northern Indians, and African-Americans. In western Europe, GCA is more common in the northern latitudes than the southern ones. The incidence of GCA has been increasing over the past

Table 88-1 American College of Rheumatology Classification Criteria for Giant Cell Arteritis

Criterion*	Definition
Age at disease onset ≥ 50 yr	Development of symptoms or findings beginning at age 50 or older
New headache	New onset or new type of localized pain in the head
Temporal artery abnormality	Temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis of cervical arteries
Elevated ESR	ESR ≥ 50 mm/hr by the Westergren method
Abnormal artery biopsy	Biopsy specimen with artery showing vasculitis characterized by a predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells

*For purposes of classification, a patient with vasculitis is said to have giant cell (temporal) arteritis if at least three of these five criteria are present. The presence of any three or more criteria yields a sensitivity of 93.5% and a specificity of 91.2%.

ESR, erythrocyte sedimentation rate.

From Hunder GG, Bloch DA, Michel BA, et al: The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis, *Arthritis Rheum* 33:1125, 1990.

20 to 40 years, possibly because of greater physician awareness.^{4,7} Some studies have reported seasonal variations and clustering of cases, with peaks about 7 years apart.^{7,10} The prevalence of GCA in Olmsted County, Minnesota, home to many Scandinavian immigrants, is 200 per 100,000 population aged 50 years or older. Autopsy studies suggest that GCA may be more common than is clinically apparent. Östberg¹³ found arteritis in 1.6% of 889 postmortem cases in which sections of the temporal artery and two transverse sections of the aorta were examined.

Genetic susceptibility to the development of GCA was initially suggested by reports of GCA in families¹⁴ and, more recently, by studies demonstrating an association with genes in the human leukocyte antigen (HLA) class II region.¹⁵ Sixty percent of GCA patients have HLA-DRB1*04 haplotype variants, which have a common sequence motif in the second hypervariable region of the B1 molecule.¹⁵ This motif differs from that found in patients with RA.¹⁵ The low prevalence of these alleles in African-Americans may explain why blacks develop GCA relatively infrequently. To date, GCA is the form of systemic vasculitis most closely associated with HLA class II genes. Susceptibility to GCA and PMR has also been associated with polymorphisms of genes for tumor necrosis factor, intercellular adhesion molecules, and interleukin 18 (IL-18).⁴

The existence of environmental risk factors has been suggested by the geographic clustering of GCA cases. Smoking appears to increase the risk of developing GCA sixfold in women.¹⁶ Circumstantial evidence links the development of GCA to a variety of infectious agents including *Mycoplasma pneumoniae*, varicella-zoster virus, parvovirus B19, and parainfluenza virus type I.^{10,11} The results of examining temporal artery biopsy specimens with polymerase chain reaction methods to detect parvovirus B19 or herpesvirus DNA have been negative or inconsistent.¹⁷ The reported association between GCA and *Chlamydia pneumoniae* infection has not withstood close scrutiny.¹⁸

Gender and health status also influence the development of GCA. Women are affected about twice as often as men.¹⁰ Having diabetes reduces the risk of developing GCA by 50% in women.² Although patients with GCA have an increased risk of developing thoracic aortic aneurysms, they do not have overall higher mortality rates.¹⁰

PMR is two to three times more common than GCA.^{4,8,9,19} In Olmsted County, Minnesota, 245 cases of PMR were diagnosed during the 22-year period from 1970 through 1991, providing an average annual incidence rate of 52.5 cases per 100,000 persons aged 50 years or older.¹⁹ The prevalence of PMR (active plus remitted cases) was

Table 88-2 Diagnostic* and Classification Criteria for Polymyalgia Rheumatica

Diagnostic Criteria of Chuang and Colleagues ² (1982)		
Age 50 yr or older		
Bilateral aching and stiffness for 1 mo or more and involving two of the following areas: neck or torso, shoulders or proximal regions of the arms, and hips or proximal aspects of the thighs		
ESR > 40 mm/hr		
Exclusion of all other diagnoses except giant cell arteritis		
Diagnostic Criteria of Healey ³ (1984)		
Pain persisting for at least 1 mo and involving two of the following areas: neck, shoulders, and pelvic girdle		
Morning stiffness lasting > 1 hr		
Rapid response to prednisone (≤ 20 mg/day)		
Absence of other diseases capable of causing the musculoskeletal symptoms		
Age older than 50 yr		
ESR > 40 mm/hr		
Classification Criteria of Dasgupta and Colleagues ^{3a} (2012)		
Age 50 years or older, bilateral shoulder aching and abnormal C-reactive protein and/or ESR†		
	Points without US (0-6)	Points with US‡ (0-8)
Morning stiffness duration > 45 min	2	2
Hip pain or limited range of motion	1	1
Absence of rheumatoid factor or anticitrullinated protein antibody	2	2
Absence of other joint involvement	1	1
At least one shoulder with subdeltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) and at least one hip with synovitis and/or trochanteric bursitis	Not applicable	1
Both shoulders with subdeltoid bursitis, biceps tenosynovitis or glenohumeral synovitis	Not applicable	1

*For each set of criteria, all the findings must be present for polymyalgia rheumatica to be diagnosed.

†A score of 4 or more is categorized as polymyalgia rheumatica in the algorithm without US, and a score of 5 or more is categorized as polymyalgia rheumatica in the algorithm with US.

‡Optional ultrasound criteria.

ESR, erythrocyte sedimentation rate; US, ultrasound.

approximately 600 per 100,000 persons aged 50 years and older.¹⁹ PMR is associated with the same *HLA-DR4* genes as GCA.^{15,20}

Cause, Pathology, and Pathogenesis

The causes of GCA and PMR are unknown. Because pathologic studies have provided important clues to the pathogenesis, they are discussed first.

In GCA, inflammation is found most often in medium-size muscular arteries that originate from the arch of the aorta.^{10,13,21,22} The inflammation tends to affect the arteries in a segmental fashion (possibly leading to “skip lesions” within arteries), but long portions of arteries may be involved.²³ In patients who died during the active phase of GCA, the greatest frequency of severe involvement was noted in the superficial temporal arteries, vertebral arteries, and ophthalmic and posterior ciliary arteries.²⁴ The internal carotid, external carotid, and central retinal arteries were affected somewhat less frequently.²⁴ In other postmortem studies, lesions were commonly found in the proximal and distal aorta and internal and external carotid, subclavian, brachial, and abdominal arteries.¹³ Because GCA affects vessels with an internal elastic lamina and vasa vasorum, and because intracranial arteries lose these structures after penetrating the dura, it is not surprising that GCA rarely involves intracranial arteries.²⁴⁻²⁶ In some patients with GCA, follow-up biopsy or autopsy surveys showed the persistence of mild chronic inflammation, even though symptoms had resolved.²

Early in the disease, collections of lymphocytes are confined to the region of the internal or external elastic lamina or adventitia. The inflammation may be limited to the vasa vasorum in some cases.³ Intimal thickening with prominent cellular infiltration is a hallmark of more advanced cases. In heavily involved areas, all layers are affected (Figure 88-1). Transmural inflammation of portions of the arterial wall (including the elastic laminae) and granulomas containing multinucleated histiocytic and foreign body giant cells, histiocytes, lymphocytes (which are predominantly CD4⁺ T cells), and some plasma cells and fibroblasts are found.^{22,27,28} Eosinophils may be seen, but polymorphonuclear leukocytes are rare. Thrombosis may develop at sites of active inflammation; later, these areas may recanalize. The inflammatory process is usually most marked in the inner portion of the media adjacent to the internal elastic lamina. Fragmentation and disintegration of elastic fibers occur, closely associated with an accumulation of giant cells (Figure 88-2). However, giant cells are seen in only about half of routinely examined specimens; therefore they are not required to make the diagnosis if other features are compatible. In contrast to some other forms of systemic vasculitis (e.g., polyarteritis nodosa, microscopic polyangiitis, granulomatosis with polyangiitis [GPA] [formerly Wegener's granulomatosis]), fibrinoid necrosis is rarely if ever observed in GCA.³

Immunohistochemical studies demonstrate inflammatory changes that are specific for each layer of the affected artery.^{11,22,28-31} Dendritic cells, which can present antigen and activate T cells, are found in the adventitia, along with two separate lineages of CD4⁺ T cells: (1) Th1 cells that secrete interferon- γ (IFN- γ) and interleukin-2 (IL-2) and (2) Th17 cells that secrete interleukin-17 (IL-17) family

Figure 88-1 Giant cell arteritis. **A**, Cross-section of a temporal artery showing transmural inflammation with mononuclear cells and giant cells (hematoxylin and eosin, $\times 10$). **B**, Higher-power ($\times 100$) view demonstrating giant cells infiltrating the media. (Courtesy Dr. Frederic Askin.)

members including IL-17A.³²⁻³⁴ The adventitial T cells show evidence of clonal expansion. The adventitia is also infiltrated with macrophages that secrete IL-1, IL-6, and transforming growth factor- β (TGF- β). The media is populated mostly by macrophages that, in contrast to those in other layers, produce matrix metalloproteinases and oxygen free radicals. Closer to the intima, the macrophages secrete nitric oxide and unite to form syncytia—the giant cells—which produce platelet-derived growth factor (PDGF) and substances that stimulate intimal proliferation.^{22,35}

Although microscopic examination of arteries in PMR is usually normal, immunohistochemical studies of apparently uninvolved temporal arteries reveal upregulation of the same macrophage-related inflammatory cytokines found in GCA.²² The T cell cytokine IFN- γ is abundantly expressed in GCA and is absent in arteries from patients having only PMR. Pathologically, relatively little else has been found in the arteries of patients with PMR. Granulomatous myocarditis and hepatitis have been noted.³⁶ Muscle biopsy specimens may be normal or show nonspecific type II muscle atrophy. However, a number of reports have shown the presence of lymphocytic synovitis in the knees, sternoclavicular joints, and shoulders and evidence of a similar

Figure 88-2 Giant cell arteritis involving the proximal aorta in a patient who died of a ruptured ascending aorta. This section of the ascending aorta is distal to the ruptured portion and shows destruction of elastic fibers (arrow) (elastic van Gieson stain, $\times 64$). Neighboring sections stained with hematoxylin and eosin showed infiltrations of mononuclear leukocytes in the areas of disrupted fibers.

reaction in sacroiliac joints.^{37,38} Synovitis (mostly subclinical) was shown in bone scans demonstrating an increased uptake of technetium pertechnetate in the joints of 2 of 25 patients with PMR.³⁷ More sensitive studies using magnetic resonance imaging (MRI) and ultrasonography have convincingly demonstrated that in PMR, the principal foci of inflammation are the bursae surrounding the shoulder more than the glenohumeral joint itself.⁵ Sera from patients with GCA, PMR, or both demonstrate evidence of systemic inflammation, with increased levels of circulating immune complexes during active disease³⁹ and elevated levels of IL-6 and IL-1.⁷

These observations, together with the results from experiments in which temporal arteries from patients with GCA have been implanted into mice with severe combined immunodeficiency (SCID), suggest that GCA results from an adaptive immune response in the wall of an artery.^{22,33} In this model (Figure 88-3) the key initiating event is activation of dendritic cells located in the adventitia, the only arterial layer normally penetrated by the vasa vasorum. In large and medium-size arteries, immunohistochemical studies reveal that the dendritic cells in temporal arteries have a specific phenotype and express fascin and CD11c.^{22,32} Dendritic cells express Toll-like receptors (TLRs) that normally serve as sentinels, monitoring for any immunologic breach of the adventitia.⁴⁰ In GCA, activation of TLRs on dendritic cells appears to be the initial triggering event.^{32,40,41} Of the many different types of TLRs, TLR-2 and TLR-4 might be the most important in GCA. Although the exact trigger of the adaptive immune response in GCA is not known, experiments in the GCA-SCID mouse model have shown that blood-borne lipopolysaccharide serves as an effective TLR ligand in temporal arteries. Other

constituents of microorganisms or some self-antigens (e.g., oxidized lipids) might also be TLR ligands that activate the arterial dendritic cells.

Once its TLRs have been engaged, dendritic cells differentiate from the resting to the active state and release cytokines such as IL-6 and IL-18, which recruit, activate, and retain CD4⁺ T cells in the blood vessel. The crucial role of dendritic cells in activating T cells and maintaining vasculitis has been demonstrated in the GCA-SCID mouse model: Depleting the dendritic cells markedly reduces the T cell infiltrate and suppresses the vasculitis. As noted, two separate populations of CD4⁺ T cells become activated and expand: IFN- γ producing Th1 cells and IL-17 producing Th17 cells. IFN- γ causes macrophages to migrate, differentiate, and form granulomas.^{34,40} Production of matrix metalloproteinases and lipid peroxidation agents by macrophages in the media results in the destruction of elastic laminae. The vessel attempts to counter the tissue destruction by elaborating a variety of growth factors including PDGF, vascular endothelial growth factor (VEGF), and TGF- β , which prompt smooth muscle cells in the media to revert from a contractile phenotype to a secretory one and migrate to the intima. Proliferation of the intimal smooth muscle cells results in occlusion of the lumen.^{22,32}

PMR appears to result from a similar but less intense adaptive immune response in blood vessels (as evidenced by the in situ production of many inflammatory cytokines). According to this model, both PMR and GCA begin with the activation of dendritic cells at the adventitia-media border.^{32,41} However, the distinguishing feature of PMR is the absence of T cells producing IFN- γ . Without IFN- γ to

Figure 88-3 Proposed model for the pathogenesis of giant cell arteritis. IFN- γ , interferon-gamma; MMPs, matrix metalloproteinases.

stimulate the recruitment and differentiation of macrophages, the level of arterial inflammation in PMR remains subclinical. Thus the development of GCA appears to require both vascular dendritic cell activation and a disease-inducing repertoire of T cells.^{22,32,41} The constitutional symptoms of PMR and GCA are attributed to the high levels of inflammatory cytokines (e.g., IL-1, IL-6) found in the sera. Whether these serum cytokine elevations result from blood vessel inflammation alone or from some other source of inflammation is not yet clear. The attractiveness of this model is increased by its ability to explain why subsets of clinical features occur together.

Clinical Features

The mean age at onset of GCA and PMR is approximately 79 years, with a range of about 50 to 90 years of age.^{10,12} Younger patients with PMR have been described occasionally. Women are affected about twice as often as men.¹⁹ Although the onset of the disease is usually insidious, typically evolving over weeks or months, in one-third of cases, the disease begins so abruptly that some patients recall the very day they became ill.^{10,36}

Giant Cell Arteritis

Classic Manifestations. The most common manifestations of GCA are constitutional symptoms, headache, visual symptoms, jaw claudication, and PMR¹⁰ (Table 88-3). Almost all patients experience one or more constitutional symptoms including fatigue, weight loss, malaise, and fever.

Besides constitutional symptoms, headache is the most common symptom in GCA, being present in nearly three-quarters of patients.⁴² The pain is typically described as boring in quality, of moderate severity, and most commonly appreciated in the temporal area. However, the description of the headache varies enormously. It can be mild to so severe that the patient seeks immediate relief by presenting to the emergency department. The pain may localize to any part of the skull including the occiput (owing to involvement of the occipital artery).^{10,13} The most consistent characteristic is that the patient experiences the headache as something new and unusual. In untreated patients, the headache may subside over weeks, even though the disease

Figure 88-4 Giant cell arteritis (GCA) involving the temporal artery. Short segments of curved artery were erythematous and tender (long arrows). The bandage on the scalp covers a similar artery that was biopsied and showed GCA. A previous biopsy specimen of a proximal segment of the right temporal artery, which was normal on physical examination, was normal histologically. The faint scar from that biopsy can be seen above and anterior to the right ear (short arrows).

activity continues. Often, the headache of GCA is not associated with any particular findings on physical examination. Abnormalities of the temporal artery—including enlargement, nodular swelling, tenderness, or loss of pulse—develop in only about half of patients (Figure 88-4). Some patients note tenderness of the scalp, which can be aggravated by brushing or combing the hair.

Visual symptoms are common in GCA, especially loss of vision and diplopia. Vision loss can be unilateral or (less commonly) bilateral, transient or permanent, and partial or complete.⁴³ Vision loss lasting more than a few hours usually does not reverse. Loss of vision often reflects an anterior ischemic optic neuropathy caused by occlusive arteritis of the posterior ciliary artery, the chief blood supply to the head of the optic nerve. The posterior ciliary artery is a branch of the ophthalmic artery (which derives, in turn, from the internal carotid artery). Less frequently, vision loss in GCA stems from a retinal artery occlusion. Regardless of the site of the culprit lesion, vision loss in GCA is usually profound, with more than 80% of patients unable to see hand waving.⁴³ GCA patients who present with fever or other systemic symptoms are less likely to develop vision loss.^{44,45} One possible explanation of this protective effect of fever and other systemic manifestations is that patients with prominent systemic inflammation demonstrate more extensive angiogenesis in temporal artery biopsies.⁶ The angiogenesis associated with increased inflammation may result in the development of collateral circulation that reduces the chance of ischemic events.⁶

The early funduscopic appearance in the setting of blindness caused by anterior ischemic optic neuropathy is that of ischemic optic neuritis: slight pallor and edema of the optic

Table 88-3 Symptoms of Giant Cell Arteritis

Symptom	Frequency (%)

Diplopia	9

Modified from Smetana GW, Shmerling RH: Does this patient have temporal arteritis? *JAMA* 287:92, 2002. Data from a review of 2475 patients reported in the literature.

Figure 88-5 Ophthalmoscopic appearance of the acute phase of anterior ischemic optic neuropathy seen in patients with giant cell arteritis and loss of vision. The optic disc is pale and swollen, the retinal veins are dilated, and several flame-shaped hemorrhages and a cotton-wool spot (retinal infarct) are visible. (Courtesy Dr. Neil R. Miller.)

disc, with scattered cotton-wool patches and small hemorrhages⁴³ (Figure 88-5). Later, optic atrophy occurs. Rarely, blindness may be the initial symptom; however, it tends to follow other symptoms by several weeks or even months. Ophthalmoscopic examination in patients without eye involvement is generally normal. In most reports, the incidence of blindness is 20% or less.^{6,43,46} In a series of 245 patients from the modern era, 34 (14%) had some permanent loss of vision.⁴⁶ In 32 of these patients, the deficit developed before glucocorticoid therapy was begun; in the other 2, vision loss occurred after therapy was started. Vision loss progressed in 3 of the 32 after therapy was initiated, and it improved in 5. At 5 years' follow-up, among the patients who had visual deficits caused by GCA at the time glucocorticoids were started, the risk of additional loss of vision was 13% over the follow-up period. If no loss had occurred at the beginning of glucocorticoid therapy, there was only a 1% risk of new loss of vision over the subsequent 5 years.

Another potential ocular complication of GCA is ophthalmoplegia. Diplopia usually results from ocular motor nerve palsies caused by ischemia and usually resolves after therapy is started. Oculomotor nerve involvement in GCA usually spares the pupil.⁴³ Rarely, arterial lesions cause infarction of the occipital cortex and vision loss.

Intermittent claudication may occur in the muscles of mastication (jaw claudication), the extremities, and occasionally the muscles of the tongue or those involved in swallowing.¹⁰ In the jaw muscles, the discomfort is noted, especially when chewing meat, and may involve the muscles on one side of the mandible more than those on the other. In some instances, facial artery involvement results in spasm of the jaw muscles. More marked vascular narrowing may lead to gangrene of the scalp or tongue.

Atypical Manifestations. Approximately 40% of patients present with disease manifestations that are

considered atypical^{33,47-49} (Table 88-4). In these patients, headache, jaw claudication, visual symptoms, and PMR do not occur or are less prominent.

Fever occurs in up to 40% of patients with GCA, but it is usually low grade and overshadowed by other classic symptoms. However, 15% of GCA patients may present with fever of unknown origin (FUO) in which the temperature spikes are high, dominating the clinical picture.^{6,36} Although GCA causes only 2% of all cases of FUO, it is responsible for 16% of all such fevers in individuals older than 65 years.³⁶ Approximately two-thirds of patients experience shaking chills and drenching sweats, features often attributed to infection or malignancy. The median temperature is 39.1° C, and the maximum 39.8° C. The white blood cell count in GCA-induced FUO is usually normal or nearly so (at least before the initiation of prednisone).

Neurologic problems occur in approximately 30% of patients.^{1,50} These are diverse, but most common are neuropathies and transient ischemic attacks or strokes. Hemiparesis or brain stem events are due to narrowing or occlusion of the carotid or vertebrobasilar artery. GCA preferentially involves the posterior circulation; the 3:2 ratio of anterior to posterior strokes and transient ischemic attacks seen in the normal population reaches nearly 1:1 in patients with GCA.⁵¹ Delirium, reversible dementia, and myelopathy have also been reported. However, the assignment of an exact cause to ischemic central nervous system events is often challenging, given the older population in which GCA occurs. The neuropathies of GCA include mononeuropathies and peripheral polyneuropathies and may affect the upper or lower extremities. Presumably, they are secondary to the involvement of nutrient arteries, but little pathologic documentation is available. Among the vasculitides, GCA has a nearly unique propensity for involving the C5 nerve root, resulting in loss of shoulder abduction.²⁵ Mononeuropathies affecting the hands and feet, so typical of polyarteritis and other forms of vasculitis, develop less often in GCA.

Table 88-4 Atypical Manifestations of Giant Cell Arteritis

Fever of unknown origin
Respiratory symptoms (especially cough)
Otolaryngeal manifestations
Glossitis
Lingual infarction
Throat pain
Hearing loss
Large artery disease
Aortic aneurysm
Aortic dissection
Limb claudication
Raynaud's phenomenon
Neurologic manifestations
Peripheral neuropathy
Transient ischemic attack, stroke
Dementia
Delirium
Myocardial infarction
Tumor-like lesions
Breast mass
Ovarian and uterine mass
Syndrome of inappropriate antidiuretic hormone secretion
Microangiopathic hemolytic anemia

Prominent respiratory tract symptoms occur in about 10% of patients.⁵² These include cough with or without sputum, sore throat, and hoarseness. When these symptoms are severe or an initial manifestation of GCA, they may direct the attention of the examining physician away from the underlying arteritis. Vasculitis may induce these symptoms by causing ischemia or hyperirritability of the affected tissues. Otolaryngeal manifestations of GCA include throat pain, dental pain, tongue pain, glossitis, and ulceration or infarction of the tongue.^{52,53}

Clinical evidence of large artery involvement occurs in 10% to 15% of cases at presentation and in up to 27% eventually.^{3,38,54} Positron emission tomography (PET) studies using fluorodeoxyglucose (FDG) revealed that subclinical involvement of large arteries occurs in the vast majority of GCA patients. One PET study, for example, showed that 88% of 35 patients had increased FDG uptake in large arteries, with subclavian involvement in 7% and aortic involvement in 54%.⁵⁵

Generally, clinically evident disease can be divided into early (within a year of diagnosis) and late (years after diagnosis) stages. Usually, early disease consists chiefly of large artery stenosis resulting in upper extremity claudication; bruits over the carotid, subclavian, axillary, and brachial arteries; absent or decreased pulses in the neck or arms; and Raynaud's phenomenon (Figure 88-6).⁵⁴ Angiographic features that suggest GCA are smooth-walled arterial stenoses or occlusions alternating with areas of normal or increased caliber in the absence of irregular plaques and ulcerations, located especially in the carotid, subclavian, axillary, and brachial arteries. Late disease most frequently involves thoracic aortic aneurysm.⁵⁴ The tendency for aneurysm to develop late was confirmed in one series of 41 patients in which the average time between diagnosis of GCA and recognition of this complication was 7 years.³⁹ Thoracic aortic aneurysm is 17 times more likely to develop in patients with GCA than in persons without this disease. To place this risk in context, thoracic aortic aneurysms are twice as likely to complicate GCA as lung cancer is to result from smoking. Abdominal aortic aneurysm is also 2.4 times more common in patients with GCA.^{3,39} In aggregate,

Figure 88-6 Arch aortogram showing giant cell arteritis of large arteries. Both subclavian and axillary arteries are affected. Smooth-walled segmental constrictions alternate with areas of normal caliber or aneurysmal dilation. (From Klein RG, Hunder GG, Stanson AW, Sheps SG: Large artery involvement in giant cell [temporal] arteritis, *Ann Intern Med* 83:806, 1975.)

nearly one out of five patients (18%) with GCA develops an aortic aneurysm or dissection.⁵⁴ Patients with large artery disease often do not have headache or other classic manifestations of GCA, and less than 50% have an abnormal temporal artery biopsy. Computed tomography (CT) angiography and magnetic resonance angiography (MRA) are the imaging modalities most commonly used to detect large artery disease in GCA.

In women, GCA can uncommonly present as a breast or ovarian mass.^{49,56} The mass lesions in these tissues result from granulomatous inflammation in and around the arteries. Angina pectoris, congestive heart failure, and myocardial infarction secondary to coronary arteritis occur rarely.

Clinical Subsets. Studies suggest that GCA is not just one disease but rather a number of clinical subsets that are explained by the differential expression of inflammatory cytokines.⁵⁷ Ischemic events including blindness, stroke, and large artery disease occur more commonly in patients who express high levels of IFN- γ and low levels of IL-6.⁵⁷ In contrast, patients who produce high amounts of IL-6 are more likely to have strong inflammatory features (such as fever and constitutional symptoms) and are less likely to develop vision loss or other ischemic events.⁵⁷⁻⁵⁹

Polymyalgia Rheumatica

As in GCA, PMR patients are characteristically in good health before their disease begins.¹⁰ Systemic manifestations such as malaise, low-grade fever, and weight loss are present in more than half the patients and may be the initial symptoms. High, spiking fevers are uncommon in PMR in the absence of GCA.³⁶ Arthralgias and myalgias may develop abruptly or evolve insidiously over weeks or months.² Malaise, fatigue, and depression, along with aching and stiffness, may be present for months before the diagnosis is made. In most patients, the shoulder girdle is the first to become symptomatic; in the remainder, the hip or neck is involved at the onset. The discomfort may begin in one shoulder or hip but usually becomes bilateral within weeks. Symptoms center on the proximal limb, axial musculature, and tendinous attachments. Morning stiffness resembling that of RA and “gelling” after inactivity are usually prominent. If the symptoms are severe, aching is more persistent. Although movement of the joints accentuates the pain, it is often felt in the proximal extremities rather than in the joints.² Distal joint pain and swelling occur in some cases including diffuse distal extremity swelling with pitting edema.⁶⁰ Pain at night is common, and movement during sleep may awaken the patient. Muscle strength is generally unimpaired, although pain with movement makes the interpretation of strength-testing maneuvers difficult. Pain with movement also makes it difficult for patients to get out of bed or the bathtub. In the later stages of the syndrome, muscle atrophy may develop, and contracture of the shoulder capsule may result in limitation of passive and active motion.

As noted, the presence of bursal inflammation and synovitis in PMR has been described by many authors and is undoubtedly the cause of many of the findings in this condition.⁵ A careful examination may reveal transient synovitis of the knees, wrists, and sternoclavicular joints.

The shoulders and hips are covered by heavy muscles, and minimal effusions of slight synovitis are not palpable on physical examination. Synovitis has been documented by biopsies, synovial analysis, joint scintiscans, ultrasonography, and MRI.³⁶⁻³⁸

Relationship between Polymyalgia Rheumatica and Giant Cell Arteritis

Evidence that PMR and GCA are related and should be considered different manifestations of a common disease process is abundant.^{10,22} The associations with age, ethnicity, geographic region, and HLA class II alleles are the same in both disorders. Moreover, both disorders involve overproduction of many of the same inflammatory cytokines. Between 30% and 50% of patients with GCA develop PMR. Approximately 10% to 15% of patients who appear to have only PMR have positive temporal artery biopsies. In the absence of symptoms of GCA (e.g., headache, jaw claudication, visual symptoms, high fever), PMR by itself does not appear to cause vision loss and responds to low doses of glucocorticoids (see later).¹⁰

Laboratory Studies

Except for the findings on arterial biopsy, laboratory results in PMR and GCA are similar (Table 88-5). A mild to moderate normochromic anemia is usually present in both diseases during their active phases. Leukocyte and differential counts are generally normal. A markedly elevated ESR and C-reactive protein (CRP) level are characteristic of both. An ESR higher than 100 mm/hr (Westergren method) is common, but untreated biopsy-proven cases of GCA may be associated with normal or nearly normal levels. In a study of 167 GCA patients, 10.8% presented with an ESR of less than 50 mm/hr and 3.6% had a rate of less than 30 mm/hr. Rare individuals appear to be unable to develop an elevated ESR during any inflammatory process including active GCA. The ESR is also liable to be relatively low or normal in patients who have been receiving corticosteroids for another condition.⁶¹ Thus a normal ESR does not exclude GCA, especially in a patient with otherwise classic symptoms and findings. Platelet counts are often increased.

Nonspecific changes in plasma proteins are often present and include a decrease in the concentration of albumin and

an increase in α_2 -globulins, fibrinogen, and other acute-phase reactant proteins. Slight increases in γ -globulins and complement may be present. Results of tests for antinuclear antibodies and rheumatoid factor are generally negative.

Liver function test results are mildly abnormal in approximately one-third of patients with GCA and in a slightly smaller fraction of those with PMR. An increased alkaline phosphatase level is the most common abnormality, but increases in aspartate transaminase and prolonged prothrombin time may also be found. Liver biopsy specimens are generally normal; granulomatous hepatitis has been observed.³⁶ Renal function and urinalysis are usually normal. Red blood cell casts are found in some instances, but their presence does not correlate with clinical large artery involvement.²³

Levels of serum creatine kinase and other enzymes reflecting muscle damage are normal. Electromyograms are usually normal, and muscle biopsy shows normal histologic features or only the mild atrophy characteristic of disuse.

Synovial fluid analyses reported in GCA or PMR show evidence of mild inflammation including increased synovial fluid leukocyte counts, with a mean of 2900 cells/mm³ but a range from 300 to 20,000 cells/mm³, with 40% to 50% being polymorphonuclear leukocytes. Synovial fluid complement levels are usually normal. In some instances, synovial biopsy has shown lymphocytic synovitis.^{37,38}

Serum IL-6 levels are elevated in patients with PMR and GCA and appear to closely parallel the inflammatory activity.⁶² Levels of factor VIII or von Willebrand factor are elevated in patients with GCA and PMR.

Differential Diagnosis

The diagnosis of GCA should be considered in any patient older than 50 years who experiences loss of vision, diplopia, new form of headache, jaw claudication, PMR, FUO, unexplained constitutional symptoms, anemia, and a high ESR. GCA can cause so many forms of cranial discomfort (e.g., headache, scalp tenderness, jaw claudication, pain of the throat, gums, and tongue) that the disease should also be considered in any patient older than 50 who develops new, unexplained "above-the-neck" pain. The protean manifestations of GCA mean that it should also be considered in the differential diagnosis of an older patient presenting with dry cough, stroke, arm claudication, or acute C5 radiculopathy accompanied by other classic symptoms or findings of GCA.

Only a few individual symptoms or findings substantially increase or decrease the likelihood of a patient having this disease⁴² (Table 88-6). For example, jaw claudication, diplopia, abnormal temporal artery signs, scalp tenderness, and ESR greater than 50 mm/hr increase the likelihood that a patient has GCA.⁴² In one series of 373 patients, the presence of either jaw claudication or diplopia increased the likelihood of a positive biopsy by more than threefold; the presence of both jaw claudication and double vision had a 100% positive predictive value for a diagnostic temporal artery biopsy.⁶³ Conversely, the absence of headache or temporal artery abnormalities on physical examination, the presence of synovitis, and a normal ESR reduce the likelihood of GCA.

Table 88-5 Physical Findings and Laboratory Abnormalities in Giant Cell Arteritis

Feature	Frequency (%)
Any temporal artery abnormality	65
Prominent or enlarged temporal artery	47
Absent temporal artery pulse	45
Scalp tenderness	31
Any funduscopic abnormality	31
Abnormal ESR	96
ESR >50 mm/hr	83
ESR >100 mm/hr	39
Anemia	44

ESR, erythrocyte sedimentation rate.

A large number of disorders can mimic GCA (Table 88-7). There are many causes of monocular vision loss besides vasculitis including arteriosclerosis-induced thromboembolic disease.⁴³ Patients with nonarteritic vision loss do not have other GCA-related symptoms, signs, or findings. The funduscopy examination may help by revealing Hollenhorst plaques in cases caused by cholesterol emboli. Anterior ischemic optic neuropathy, the most common cause of vision loss in GCA, can also be caused by arteriosclerosis. Nonarteritic optic neuropathy invariably produces a small optic disc and cup-to-disc ratio, whereas GCA-related optic neuropathy results in an optic disc of variable size.⁴³ Thus a normal size or large cup in a patient with anterior ischemic optic neuropathy suggests GCA until proved otherwise.⁴³

Constitutional symptoms with anemia and an elevated ESR in an older person may also be produced by occult infections (e.g., tuberculosis, bacterial endocarditis, human immunodeficiency virus [HIV]) or malignancy (especially lymphoma and multiple myeloma). These diagnoses highlight the value of selective serologic tests, imaging studies, and immunoelectrophoresis in appropriate patients. Systemic amyloidosis can closely mimic GCA, being one of the few disorders other than GCA that causes jaw claudication. The amyloid deposits in the temporal artery may not be detected unless the specimen is stained with Congo red. Polyarthritides in an older patient is much more likely caused

by RA than by GCA. In one study of 520 GCA patients, less than 2% developed polyarthritides before GCA was diagnosed.

Criteria for the classification of GCA have been formulated and can help differentiate this arteritis from other forms of vasculitis⁶⁴ (see Table 88-1). Takayasu's arteritis, like GCA, can affect the aorta and the major arterial branches to the head and arms. Takayasu's arteritis, however, is a disease of young women. Antineutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis can affect the temporal artery and, along with systemic amyloidosis, is an exception to the rule that jaw claudication is pathognomonic for GCA. AGV, however, almost always produces telltale involvement of the respiratory tract or kidneys and is associated with ANCA. Polyarteritis nodosa can also affect the temporal artery and should be considered if the biopsy does not contain giant cells and the patient has other features atypical for GCA such as mesenteric arteritis. Fibrinoid necrosis of the vasa vasorum occurs in polyarteritis but rarely, if ever, in GCA. Primary angiitis of the central nervous system differs from GCA in that it affects the intracranial arteries.

The diagnosis of PMR is clinical and depends on eliciting the symptoms and findings noted earlier. Two sets of criteria for the diagnosis have been proposed^{2,3} (see Table 88-2). Several disorders can mimic PMR (see Table 88-7). Distinguishing early RA from PMR can be difficult, especially in the 15% of patients who are rheumatoid factor negative and in those few RA patients who have not yet developed prominent synovitis of the small joints of the hands and feet. Patients with polymyositis complain much more of weakness than of pain—the opposite symptom pattern reported by patients with PMR. In addition, in polymyositis, levels

Table 88-7 Differential Diagnosis of Giant Cell Arteritis and Polymyalgia Rheumatica

Disease Type	Specific Entities
Giant Cell Arteritis	
Occult infections	Tuberculosis, bacterial endocarditis, human immunodeficiency virus
Malignancy	Lymphoma and multiple myeloma
Systemic amyloidosis	—
Other forms of vasculitis	Takayasu's arteritis, antineutrophil cytoplasmic antibody-associated granulomatous vasculitis, polyarteritis nodosa, primary angiitis of the central nervous system Other vascular disorders causing anterior ischemic optic neuropathy
Polymyalgia Rheumatica	
Early rheumatoid arthritis	—
Polymyositis	—
Chronic infections	Bacterial endocarditis
Fibromyalgia	—
Complication of medication	Statins
Endocrine disorders	Hypothyroidism
Remitting, seronegative synovitis with pitting edema	—

of muscle enzymes are elevated and electromyograms are abnormal. Although patients with neoplasms may have generalized musculoskeletal aching, there is no association between PMR and malignant neoplasia. Therefore a search for an underlying tumor is not necessary unless some clinical evidence for a tumor is present or the patient has an atypically poor response to low-dose prednisone.

Some patients with chronic infections such as bacterial endocarditis may have findings simulating PMR, and blood cultures should be obtained in patients with fever. Patients with fibromyalgia usually do not have typical morning stiffness and have laboratory test results that are normal or nearly so. Rarely, the stiffness of early Parkinson's disease can be confused with PMR if the bradykinesia and tremor of Parkinson's disease are subtle or absent. Lumbar spinal stenosis sometimes causes patients to complain of pain and stiffness in the hip girdle area. The absence of symptoms above the waist helps differentiate it from PMR. Cholesterol-lowering statin drugs can produce myalgia with or without muscle enzyme elevations but rarely mimic PMR. Hypothyroidism in the elderly can mimic many conditions including PMR. A peculiar syndrome of remitting, seronegative synovitis with pitting edema (designated RS₃PE syndrome) may be difficult to differentiate from PMR, and they may be related disorders. Patients with the RS₃PE syndrome develop acute symmetric polysynovitis of distal joints with pitting edema of the hands and feet. The RS₃PE syndrome and PMR both respond to nonsteroidal anti-inflammatory drugs (NSAIDs) and low-dose prednisone.^{10,64}

Diagnostic Evaluation in Giant Cell Arteritis

Temporal artery biopsy is the “gold standard” for diagnosing GCA.^{10,65} Because GCA does not involve the artery in a continuous fashion, temporal artery biopsy should be directed to the symptomatic side, if evident. Removing a small (1- to 2-cm) section of temporal artery is usually adequate in patients who have palpable abnormalities of the vessel.⁶⁶ Otherwise, the surgeon should try to excise a 4- to 6-cm sample, and the pathologist should examine multiple sections.¹⁰ In skilled hands, temporal artery biopsy is virtually free of morbidity or mortality. Scalp necrosis can rarely complicate active GCA but has not developed as a consequence of temporal artery biopsy.⁶⁵

Temporal artery biopsies performed at institutions experienced in treating GCA are sensitive and have a high negative predictive value. At the Mayo Clinic, the sensitivity of temporal artery biopsy is approximately 90% to 95%, meaning that only 5% to 10% of patients with negative biopsies will subsequently be proved (by additional biopsy, angiography, or autopsy) to have GCA and require corticosteroid therapy.⁶⁵ The sensitivity figures noted previously include some patients who underwent bilateral temporal artery biopsy. Estimates of the value of bilateral biopsies vary.^{64,67,68} Of 234 cases of biopsy-proven GCA, unilateral biopsy was positive in 86% and the second biopsy was positive in 14%.⁶⁴ Other studies indicate that a second temporal artery biopsy improves the diagnostic yield by only 3% to 5%.⁶⁸

Management of a patient with a negative unilateral biopsy depends on how strongly the patient's clinical picture suggests GCA (Figure 88-7). When GCA is still strongly

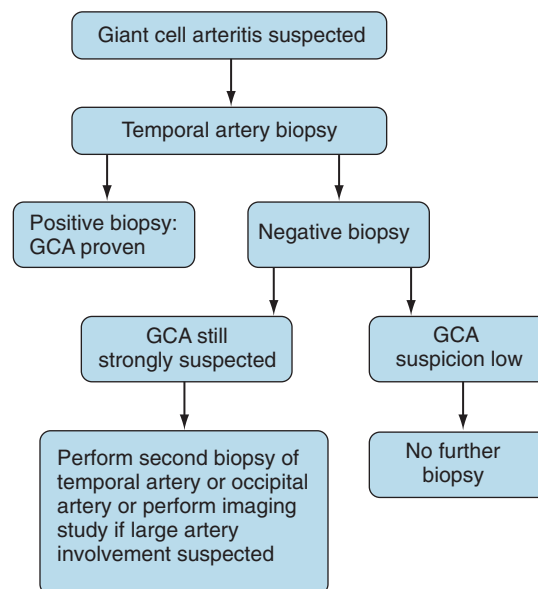

Figure 88-7 Algorithm for diagnosing giant cell arteritis (GCA).

suspected, a second biopsy or an imaging test (see later) should be considered. Opting for a second temporal artery biopsy probably makes most sense in patients who have jaw claudication or diplopia. Patients with chiefly occipital headache may be best diagnosed by biopsy of the occipital artery.⁶⁹ Patients who have signs of subclavian and axillary disease manifested by arm claudication, unequal arm blood pressures, and supraclavicular or axillary bruits may be diagnosed by angiogram, MRA, or CT scan.⁵⁷ Typically, patients with extracranial GCA have smooth, tapered stenosis or occlusion of the subclavian, axillary, and proximal brachial arteries. In one series, temporal artery biopsy was positive in only 58% of patients with larger artery involvement.⁵⁷ MRI and CT are the best-established methods for detecting aortic involvement by GCA.¹⁰

Other imaging techniques have been proposed to assist in the diagnosis of GCA. Color duplex ultrasonography showed abnormalities of the temporal artery in 28 of 30 patients with GCA (sensitivity of 93%).⁷⁰ The most characteristic finding was a dark halo around the lumen of the temporal artery (Figure 88-8). However, the diagnostic value of ultrasonography is undermined by the absence of expertise with this technique at most medical centers and conflicting estimates of its sensitivity and specificity.⁷¹⁻⁷³ One meta-analysis of 2036 patients in 23 studies estimated that the sensitivity and specificity of the halo sign were 69% and 82%, respectively. Another study found that ultrasonography did not improve the diagnostic accuracy of a carefully performed physical examination.⁷⁴ High-resolution MRI can demonstrate contrast enhancement and mural thickening of superficial cranial arteries in GCA. Small studies have found a sensitivity of 91% and a specificity of 73% compared with temporal artery biopsy.⁷¹⁻⁷³ Best results are achieved with 3-Tesla MRI scanners.⁷³ PET has shown promise in detecting occult involvement of the aorta and great vessels by GCA; however, estimates of sensitivity have varied from 65% to 100% and specificity from 77% to 99%.^{71,73} PET scanning cannot image small arteries that are near highly metabolic tissues such as the brain and thus

Figure 88-8 Color duplex ultrasound examination of a swollen, tender temporal artery in a patient with giant cell arteritis. The variably thickened artery wall is visible as a clear “halo” (solid arrows) around the lumen in the center (open arrow). (Courtesy Dr. Gene Hunder.)

cannot be used to study superficial extracranial arteries. Repeated PET scans do not predict the risk of relapse.⁷³ For the rare patient who has a compelling story for GCA but negative, bilateral temporal artery biopsies, one should reconsider conditions that mimic GCA described earlier (e.g., ask the pathologist to stain the biopsied arteries with Congo red to rule out systemic amyloidosis). If no other diagnosis becomes evident, then it is reasonable to search for occult large vessel disease with an imaging test such as a PET scan or MRA to look for occult aortic disease. Rarely, a patient's clinical picture strongly indicates GCA despite negative biopsies and imaging. In this case the patient can be treated for GCA while watching vigilantly for the emergence of another disease.

Treatment and Course

Most authorities recommend starting glucocorticoid therapy as soon as the diagnosis of GCA is strongly suspected. The main goal of treatment is to prevent loss of vision. Because vision loss is almost always permanent, it seems prudent to initiate corticosteroid therapy as early as possible, even before the biopsy is performed. Fortunately, the diagnostic yield of temporal artery biopsy is not altered by corticosteroid therapy for at least 2 weeks and perhaps longer.⁷⁵

Initial Treatment for Giant Cell Arteritis

An initial dose of prednisone 40 to 60 mg/day or equivalent is adequate in nearly all cases.¹⁰ Dividing the dose for the first 1 to 2 weeks may accelerate the rate of improvement. If the patient does not respond promptly, the dose should be increased. One double-blind, placebo-controlled, randomized trial involving 27 GCA patients suggested that initiating treatment with intravenous methylprednisolone (15 mg/kg of ideal weight per day) for 3 days allowed more rapid tapering of oral corticosteroids and increased the likelihood of achieving a sustained remission.⁷⁶ The small size of that study and the possible overreliance on laboratory tests to define relapse raise questions about the generalizability of these results. High-dose, intravenous-pulse methylprednisolone (1000 mg/day) for 3 days has also been tried

in patients with recent loss of vision. Unfortunately, the loss remains permanent in the vast majority of patients. The occlusive nature of the vasculitis argues against any role of acute thrombolytic therapy in the treatment of blindness.

Because all patients with GCA require months of glucocorticoid therapy, measures to prevent osteoporosis should be started early, as outlined in Table 88-8. In addition, because traditional risk factors for atherosclerosis (e.g., smoking, hypertension, diabetes, hypercholesterolemia) might increase the risk of vision loss or stroke in GCA,⁴⁵ reducing or eliminating these risk factors is an important part of overall management.

Subsequent Treatment for Giant Cell Arteritis

The initial effective dose of prednisone should be continued until all reversible symptoms, signs, and laboratory abnormalities have reverted to normal.¹⁰ This usually takes 2 to 4 weeks. After that, the dose can be gradually reduced by a maximum of 10% of the total dose each week or every 2 weeks.¹⁰ The decision to reduce prednisone should be based on a composite assessment of the patient's symptoms, signs, and laboratory markers of inflammation. The ESR and serum concentration of CRP are generally the most convenient and helpful laboratory markers of inflammation. The ESR is reliable only if performed promptly after the blood sample is obtained. Serum levels of IL-6 appear to be the most sensitive marker of activity of GCA, but this test is not widely available.⁷⁷ CRP may be slightly more sensitive than ESR in detecting flares.⁷⁷ At some point during drug tapering, the ESR or CRP may rise above normal again, and further reductions of prednisone should be temporarily interrupted. If, over the next week or so, the patient does not develop signs or symptoms of active GCA, reductions in prednisone (at smaller decrements and at longer intervals) can usually be resumed. Doses of 10 to 20 mg/day or more are often required for several months before further reductions are possible. However, making the prednisone dose a slave to the levels of inflammatory markers without regard to the patient's overall clinical context risks corticosteroid-related side effects. Gradual reductions allow the identification of the minimal suppressive dose and help avoid exacerbations resulting from too-rapid tapering. Even with a gradual reduction of prednisone, more than 50% of

Table 88-8 Measures to Prevent Corticosteroid-Induced Osteoporosis in Giant Cell Arteritis or Polymyalgia Rheumatica

Avoid or stop smoking
Reduce alcohol consumption if excessive
Participate in weight-bearing exercise
Supplement diet with calcium (1000 to 1500 mg/day)
Supplement diet with vitamin D (800 IU/day)
Measure BMD at lumbar spine and hip
If BMD is normal, repeat BMD annually
If BMD is not normal (i.e., T score below −1), prescribe bisphosphonate

BMD, bone mineral density.

Modified from American College of Rheumatology Ad Hoc Committee on Glucocorticoid-Induced Osteoporosis: Recommendations for the prevention and treatment of glucocorticoid-induced osteoporosis, *Arthritis Rheum* 44:1496, 2001.

patients experience flares of disease activity during the first year.⁷⁸ These exacerbations can usually be handled by increasing the prednisone 10 mg above the last dose at which the disease was controlled.

Most patients with GCA have a chronic disease that requires prednisone treatment for at least 1 year and often for several years; a minority of patients run a self-limited course of only several months.¹⁰ Glucocorticoids can eventually be reduced and discontinued in some patients. Many patients require low doses of prednisone for several years or more to control musculoskeletal symptoms.

The nearly universal experience of serious side effects associated with daily corticosteroids has prompted the search for alternative steroid-sparing treatments. Unfortunately, to date, none has been convincingly effective. Alternate-day prednisone, for example, is not effective initial therapy for GCA. The combination of weekly low-dose oral methotrexate and prednisone was steroid sparing in one placebo-controlled, double-blind treatment trial but not in another.⁷⁸ These conflicting results argue against using methotrexate in combination with prednisone as initial therapy for GCA. Methotrexate may be worth adding to the treatment regimen of a patient who has experienced several exacerbations despite slow tapering of prednisone. Although open-label studies suggested that anti-tumor necrosis factor (TNF) agents might be effective in a granulomatous vasculitic process, neither infliximab nor etanercept is effective in GCA.^{79,80} In fact, in a treatment trial of patients with GPA, etanercept in combination with cyclophosphamide increased the number of solid tumors compared with cyclophosphamide alone. Similarly, cytotoxic drugs, dapsone, antimalarials, and cyclosporine have not been clearly shown to be effective, but they may be considered in patients who cannot achieve an acceptably low dose of prednisone.¹⁰

No prospective, double-blind trials have tested the potential adjunctive role of aspirin or anticoagulants in the treatment of GCA. However, aspirin is theoretically appealing because, in experimental models of GCA, it inhibits IFN- γ production more effectively than prednisone.⁸¹ In addition, two retrospective studies found that GCA patients taking low-dose aspirin or anticoagulant therapy had a threefold to fivefold lower risk of developing an ischemic event such as vision loss.^{82,83} Together, these studies suggest that it is reasonable to add low-dose aspirin in GCA patients who do not have an excessive risk of gastrointestinal bleeding.

Arm claudication from GCA affecting the subclavian and axillary arteries usually improves or resolves with corticosteroid therapy. Rare GCA patients with severe upper extremity claudication unresponsive to corticosteroid therapy may benefit from balloon angioplasty. In one series of 10 patients, all improved initially after angioplasty but 50% developed symptomatic restenosis over 2 months.⁸⁴ In all cases, recurrent stenosis developed in vascular lesions that were greater than 3 cm long.⁸⁴

Thoracic aortic aneurysm is greatly increased in patients with GCA. Although it can be present at the outset, aneurysms are usually noted late in the disease course, an average of 7 years after onset. Some authorities have recommended annual chest radiographs to detect thoracic aortic aneurysms.

Treatment for Polymyalgia Rheumatica

Patients with PMR without symptoms or signs or biopsy evidence of GCA are usually treated initially with prednisone 10 to 20 mg/day or equivalent.⁸⁵ A systematic review of 30 studies recommended starting treatment with prednisone at 15 mg/day: Lower initial doses were less effective and higher doses were more toxic.⁸⁶ Salicylates and NSAIDs have been used but are less appealing; salicylates and NSAIDs adequately control symptoms in only a minority of patients with milder symptoms and add to overall adverse drug reactions when they are used with glucocorticoids.^{2,7} Prednisone therapy usually results in rapid (often overnight) and dramatic improvement of the musculoskeletal aching and stiffness and a more gradual return of the ESR and CRP level to normal. A minority of patients with isolated PMR fails to respond to prednisone 20 mg/day after 1 week and may require up to 30 mg/day as initial treatment. Studies suggest that these resistant cases are more likely to have ESRs greater than 50 mm/hr and high levels of IL-6. Failure to respond to prednisone 30 mg/day for 1 week should prompt a search for an alternative diagnosis (Figure 88-9). Lower doses of prednisone might not suppress an underlying arteritis if it is present. Thus the patient must be observed carefully even though the aching improves. In patients with PMR, the dose should be reduced gradually as soon as symptoms permit. Pretreatment ESR, CRP, and IL-6 concentrations and initial responses to therapy appear to be helpful in dividing patients into subsets with different treatment requirements.⁸⁵ If the laboratory test results become normal while the patient is receiving a smaller dose, the likelihood of an underlying active vasculitis seems to be much less, and the risk of vascular complications is smaller. However, this is not true in all instances because active arteritis has been observed even though the ESR improved.

Once the symptoms, signs, and laboratory abnormalities of PMR have resolved (usually after 2 to 3 weeks of therapy), the daily dose of prednisone can be slowly tapered. Some experts recommend tapering prednisone by 2.5 mg every week until 10 mg/day is reached, at which point the decrements should be reduced by 1 mg each month.⁸⁶ Flares are common, necessitating a dose increase to achieve remission before attempting a slower taper. The minority of patients with PMR succeed in tapering off prednisone in less than 1 year. Many require at least 2 years of low-dose prednisone.⁸⁷

Some, but not all, studies suggest that oral methotrexate (10 mg once a week for 48 weeks) can reduce the long-term need for corticosteroids in patients with PMR.^{86,88} It is not yet known whether the small but statistically significant reduction in prednisone use achieved with methotrexate results in a clinically important reduction in prednisone-related side effects.

TAKAYASU'S ARTERITIS

Takayasu's arteritis (TA), also known as *pulseless disease* or *occlusive thromboarteropathy*, is a form of vasculitis of unknown cause that chiefly affects the aorta and its major branches, most frequently in young women.^{89,90} The disease is named for the Japanese ophthalmologist who in 1908 described a young woman with peculiar retinal arteriovenous

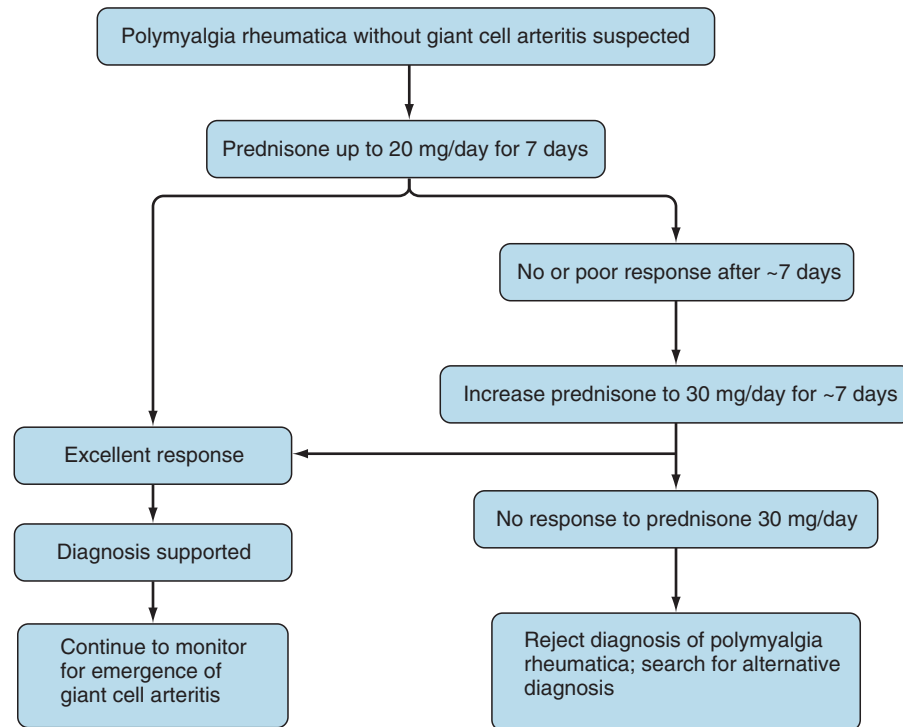

Figure 88-9 Algorithm for diagnosing polymyalgia rheumatica without giant cell arteritis.

anastomoses caused by retinal ischemia from large vessel vasculitis.¹

American College of Rheumatology Criteria

The ACR classification criteria for the diagnosis of TA are listed in Table 88-9.

Epidemiology

Although TA has been described worldwide, it occurs most commonly in Japan, China, India, and Southeast Asia; the disease is also prevalent in Mexico. Whereas the incidence of TA in Japan is nearly 150 per million per year, it is only 0.2 to 2.6 per million in western Europe and North America. TA affects women eight times more frequently than men. The median age of onset is 25 years; however, approximately 25% of cases begin before age 20, and 10%

to 20% present after age 40.⁸⁹ Immunogenetic studies in Japanese patients suggest an association with several HLAs, especially HLA-Bw52, Dw12, DR2, and DQw1. Different HLA associations have been found in Koreans and Indians. No HLA association has been found in North American patients. In Mexican patients, TA has been associated with previous exposure to *Mycobacterium tuberculosis*.

Cause and Pathogenesis

The cause of TA is unknown. The nearly identical pathology in TA and GCA has invited speculation that the model of immunopathogenesis of GCA described earlier (see Figure 88-3) applies to TA as well.^{22,40} Indeed, some have argued that TA and GCA represent a spectrum within the same disease. Like GCA, TA is thought to result from an autoimmune process that targets large elastic-containing arteries. Both feature panarteritis involving infiltration of dendritic cells; T cells (including $\alpha\beta$, $\gamma\delta$, and cytotoxic); natural killer cells; and macrophages. In TA, the majority of lymphocytes are perforin-secreting killer lymphocytes such as T cells and natural killer cells. The T cell receptors in TA, as in GCA, are oligoclonal, suggesting that the vasculitis is driven in both diseases by a T cell response to a specific but unknown antigen.⁹¹ Chronic inflammation of the vessel wall leads to aneurysm formation, stenosis, or thrombosis more frequently in TA than in GCA. Dissection occurs in TA but is rare and less frequent than in syphilitic aortitis.⁹² The late phase of TA, like that of GCA, is characterized by intima proliferation with superimposed atherosclerosis, medial necrosis with scarring, and adventitial fibrosis. As in GCA, the inflammatory involvement in TA can be continuous or segmental, with skip areas of normal vessel interposed between involved areas.⁹² It is possible

Table 88-9 American College of Rheumatology Classification Criteria for Takayasu's Arteritis*

Onset before age 40 yr
Limb claudication
Decreased brachial artery pulse
Unequal arm blood pressure (>10 mm Hg)

*The presence of three or more of the six criteria is sensitive (91%) and specific (98%) for the diagnosis of Takayasu's arteritis.

American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis, *Arthritis Rheum* 33:1129, 1990. From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment*, New York, 2004, Lange Medical Books/McGraw-Hill, p 245.

that the humoral immune system may play some role in the pathogenesis of TA; most TA patients possess antiendothelial cell antibodies that can damage vessels by inducing endothelial inflammatory cytokine production, adhesion molecules, and apoptosis.

The geographic clustering of cases has suggested that genetics and environmental factors participate in the pathogenesis of TA. However, immunogenetic studies (described earlier) have not identified any other universally shared genetic risk factors. The young age of onset and the female predominance in TA and in systemic lupus erythematosus have invited speculation about the influence of female hormones in promoting an autoimmune disease process. In some countries, the apparent association of TA with high rates of exposure to tuberculosis has suggested an infectious cause. An animal model of TA has been produced in mice using a herpesvirus that infects the smooth muscle cells of the media. In that model, the media of large elastic arteries serves as an immunoprivileged site that allows the herpesvirus to propagate a chronic inflammatory response in the aorta and its major branches.⁹³

Clinical Features

Symptoms and Signs

Although the presenting manifestations of TA are protean, the vast majority of patients present with symptoms and signs of vascular insufficiency (from stenosis, occlusion, or aneurysm); systemic inflammation; or both.^{74,89} (Table 88-10). In a North American series of 60 patients followed at the National Institutes of Health, the most common presenting vascular symptoms were claudication (35%), reduced or absent pulse (25%), carotid bruit (20%), hypertension (20%), carotidynia (20%), lightheadedness (20%), and asymmetric arm blood pressures (15%).⁸⁹ Stroke, aortic regurgitation, and visual abnormalities were present at onset in less than 10% of patients. The extreme manifestations of retinal ischemia noted in Takayasu's original patient are rarely seen now.⁸⁹ Permanent loss of vision, the major concern in GCA, rarely develops in TA.

Claudication affects the arms at least twice as frequently as the legs. For many young women, arm claudication first reveals itself as arm pain or fatigue experienced while trying to hold a hair dryer. Overall, bruit is the most common sign, eventually found in 80% of patients. Although bruit over the carotid artery is most frequent, it can also be found in the supraclavicular, infraclavicular, axillary, flank, chest, abdominal, and femoral areas. One-third of patients have multiple bruits.⁸⁹ Unequal arm blood pressures eventually develop in half of all patients. Headache, which is common in TA, does not correlate with carotid or vertebral disease, which develops in nearly 40% of patients.^{89,94}

Constitutional, musculoskeletal, and other symptoms of systemic inflammation are also common presenting complaints.^{74,89} About one in five TA patients presents with fever and malaise, which can be accompanied by night sweats and weight loss. A few patients who have minimal or no signs of vascular insufficiency may appear to have FUO for weeks or months before the diagnosis of TA becomes evident. A minority of patients present with

Congestive heart failure	2	10

Data based on a study of 60 North American patients reported by Kerr GS, Hallahan CW, Giordano A, et al: Takayasu arteritis, *Ann Intern Med* 120:919, 1994. From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment*, New York, 2004, Lange Medical Books/McGraw-Hill, p 243.

myalgia or arthralgia (see Table 88-10). Some patients have striking midthoracic back pain, perhaps as a result of aortic inflammation irritating nociceptive nerve fibers.

Cardiac involvement occurs eventually in nearly one-third of patients (see Table 88-10).⁸⁹ Aortic regurgitation develops in 20% of patients as a result of aortic root dilation. Aortic regurgitation is important because it frequently progresses and may lead to left ventricular dilation with secondary mitral regurgitation and congestive heart failure. Aortic valve replacement is often required eventually. Angina can develop as a result of coronary artery disease. TA of the coronary arteries most often produces ostial lesions but can also produce either diffuse vasculitis of the coronary arteries or aneurysms.⁹⁵⁻⁹⁷ Myocarditis also occurs in TA and causes potentially reversible congestive heart failure. Pericarditis is rare. TA is, along with Behçet's disease, one of the few forms of vasculitis that can affect the large pulmonary arteries. Although TA of the pulmonary arteries is rare (<3%), affected patients can present with cough, chest wall pain, dyspnea, or hemoptysis.

Unlike polyarteritis or GPA, TA rarely causes peripheral neuropathies. Cutaneous manifestations develop in less than 10% of patients with TA.⁸⁹ Erythema nodosum is most common, but purpura, livedo reticularis, and ulceration may rarely occur. As in GCA, a minority of TA patients with active disease have a persistent, dry cough.

Laboratory Findings

At presentation, the ESR is more frequently elevated (80%) than the CRP ($\approx 50\%$).⁷⁴ Mild anemia and hypergammaglobulinemia are common. The white blood cell count is usually normal or slightly elevated. The platelet count is elevated in one-third of patients and may exceed $500,000/\mu\text{L}$ in those with active disease. The serum creatinine and urinalysis are usually normal. Any renal abnormalities are usually secondary to hypertension; unlike ANCA-associated vasculitis, TA rarely causes glomerulonephritis.

Imaging Studies

Vascular abnormalities in TA can be imaged by conventional angiography, MRI, MRA, CT angiography, or ultrasonography.^{24,71,73,89,98} (Figures 88-10 to 88-12). Each imaging technique has advantages and disadvantages (Table 88-11). The earliest detectable abnormality in TA is thickening of the vessel wall from inflammation. MRI, ultrasonography, and, to a lesser degree, CT can detect this early vessel wall thickening. Conventional angiography is invasive and provides the least sensitive method for visualizing wall thickening; however, conventional angiography is the “gold standard” for precisely delineating the stenoses, occlusions,

Figure 88-11 Magnetic resonance image (sagittal section) through the chest showing thickening of the ascending and descending thoracic aorta in a 26-year-old woman with Takayasu's arteritis. (From Hellmann DB, Flynn JA: *Clinical presentation and natural history of Takayasu's arteritis and other inflammatory arteritides*. In Perler BA, Becker GJ, editors: *Vascular intervention: a clinical approach*, New York, 1998, Thieme Medical and Scientific Publisher, pp 249–256.)

Table 88-11 Comparison of Imaging Techniques in Takayasu's Arteritis

Technique	Advantages	Disadvantages
Conventional angiography	"Gold standard" image quality Allows CAP measurement Allows angioplasty at same time	Invasive Radiation exposure Does not visualize vessel wall thickness
Magnetic resonance angiography	Excellent image quality Noninvasive No ionizing radiation exposure Visualizes vascular wall thickness	Image quality not "gold standard" Cannot use in patients with pacemaker CAP measurement not possible
Ultrasonography	Noninvasive No ionizing radiation exposure Can visualize vessel wall edema	Image quality not "gold standard" Image quality affected by obesity Operator dependent CAP measurement not possible
Computed tomography angiography	Excellent image quality	Ionizing radiation exposure CAP measurement not possible Intravenous contrast agent required
Positron emission tomography	Can measure intensity of vascular inflammation	Ionizing radiation exposure Vascular anatomy not well seen CAP measurement not possible Intravenous contrast agent required

CAP, central arterial blood pressure.

and aneurysms that characterize the latter stages of TA. Also, only conventional angiography allows the direct measurement of central arterial blood pressure, which may be otherwise unobtainable in patients with stenotic lesions affecting all four extremities. Although MRA does not provide the same level of detail as conventional angiography, it comes close. Because MRA is not invasive and does not involve ionizing radiation, it has become the preferred imaging method for assessing the extent of vascular involvement and damage, both initially and during follow-up. The role of MRI in assessing disease activity is not clear because vessel wall edema and contrast enhancement have not correlated well with clinical measures of disease activity.⁷³ Although PET scanning would be expected to be more sensitive than angiography in the early detection of vascular inflammation that precedes the development of stenoses, its sensitivity may be no greater than MRI. PET scanning has no established role in following disease activity in TA. Indeed, one study of 28 TA patients showed that PET scans did not correlate with clinical, biologic, or MRI assessment of disease activity.⁹⁹

The most common sites of lesions in TA are the aorta (65%) and the left subclavian arteries (93%)⁸⁹ (Table 88-12). The left subclavian artery is affected slightly more frequently than the right. Carotid, renal, and vertebral arteries are also commonly affected.⁸⁹ Lesions may be stenotic (93%), occluded (57%), dilated (16%), or aneurysmal (7%). Stenotic lesions are about four times more common than aneurysmal lesions.⁸⁹ Stenotic segments often extend a few centimeters and may be followed by areas of dilation (see Figure 88-10). The majority of patients (53%) have vascular lesions above and below the diaphragm. However, the frequency distribution of aortic lesions varies considerably from country to country.⁸⁹

Diagnosis and Diagnostic Tests

The ACR has established classification criteria for the diagnosis of TA (see Table 88-9). In clinical practice, the diagnosis of TA is almost always secured by an imaging procedure (see Table 88-11) that demonstrates the characteristic

abnormalities of the aorta and its major branches (Figure 88-13). Rarely, the diagnosis is first suggested when a pathologist finds granulomatous inflammation in a section of aorta or other larger artery that was removed or biopsied during a vascular surgery procedure. Unfortunately, the diagnosis of TA is often delayed; the delay averaged 44 months in one large series. The most frequent impediment to a speedy diagnosis is a physician's failure to consider TA in the differential diagnosis. Although the rarity of TA helps explain its omission from diagnostic consideration, another reason is that some patients have striking features of inflammation that camouflage or overshadow the somewhat more familiar vascular abnormalities. Indeed, a few patients with TA present chiefly with FUO. Most of these patients have other, albeit subtle, manifestations of TA such as bruits, diminished pulses, unequal arm blood pressures, or aortic regurgitation. In other patients with more striking vascular abnormalities, the physician might be lured into focusing on familiar and dramatic abnormalities such as anemia or thrombocytopenia. Thus instead of ordering an imaging test that would explain the patient's unequal and low blood pressure in the left arm, the physician mistakenly

Table 88-12 Frequency of Blood Vessel Involvement in Takayasu's Arteritis

Blood Vessel	% Abnormal
Aorta	65
Aortic arch or root	35
Abdominal aorta	47
Thoracic aorta	17
Subclavian artery	93
Common carotid artery	58
Renal artery	38
Vertebral artery	35
Celiac axes	18
Common iliac artery	17
Pulmonary artery	5

Data based on a study of 60 North America patients reported by Kerr GS, Hallahan CW, Giordano A, et al: Takayasu arteritis, *Ann Intern Med* 120:919, 1994. From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment*, New York, 2004, Lange Medical Books/McGraw-Hill, p 245.

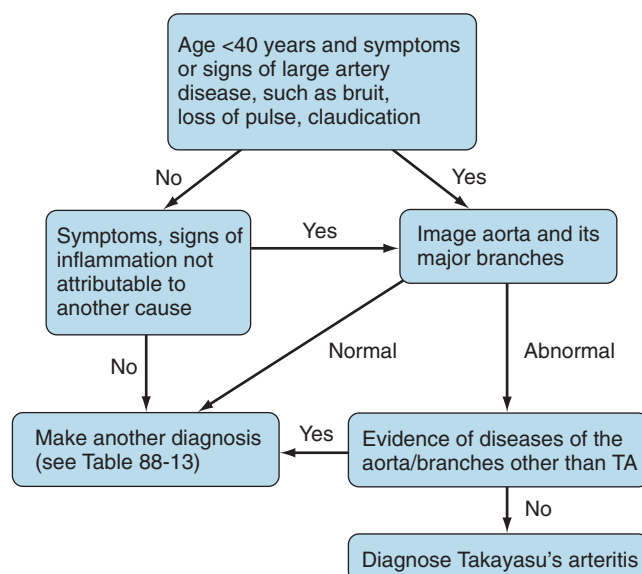

Figure 88-13 Algorithm for the diagnosis of Takayasu's arteritis (TA).

diverts the patient to a hematologist, gastroenterologist, or oncologist for additional blood tests and procedures that further delay the diagnosis.

Many of these delays can be prevented by remembering that TA should be included in the differential diagnosis of any person younger than 40 years who presents with FUO, aortic regurgitation, hypertension, or unequal or absent pulses. Delays in diagnosis can also be reduced by carefully searching for unequal or absent upper extremity pulses and by listening for bruits not only over the carotid arteries but also above and below the clavicle (for subclavian artery bruits) and over the abdomen and flanks (for renal and other mesenteric artery bruits). Recognizing that anemia and thrombocytosis can be manifestations of active inflammatory disorders such as vasculitis can also help speed the diagnosis of TA.

Once an imaging test demonstrates disease of the aorta or its major branches, the differential diagnosis narrows to a set of disorders that are usually easily differentiated (Table 88-13). Most rheumatic diseases that can affect the aorta are distinguished by their associated features. For example,

Table 88-13 Differential Diagnosis of Takayasu's Arteritis: Other Diseases That Can Affect the Aorta

Disease Type	Specific Entities
Rheumatic	Giant cell arteritis, Cogan's syndrome, relapsing polychondritis, ankylosing spondylitis, rheumatoid arthritis, systemic lupus erythematosus, Buerger's disease, Behçet's disease
Infectious	Syphilis, tuberculosis
Other	Atherosclerosis, ergotism, radiation-induced damage, retroperitoneal fibrosis, inflammatory bowel disease, sarcoidosis, neurofibromatosis, congenital coarctation, Marfan's syndrome, Ehlers-Danlos syndrome, IgG4-related systemic disease

From Hellmann DB: Takayasu arteritis. In Imboden JB, Hellmann DB, Stone JH, editors: *Current rheumatology diagnosis and treatment*, New York, 2004, Lange Medical Books/McGraw-Hill, p 243.

Table 88-14 Comparison of Giant Cell Arteritis and Takayasu's Arteritis

Feature	Giant Cell Arteritis	Takayasu's Arteritis
Female-male ratio	2:1	8:1
Age range (yr)	≥50	<40
Average age of onset (yr)	72	25
Visual loss	10%-30%	Rare
Involvement of aorta or its major branches	25%	100%
Histopathology	Granulomatous arteritis	Granulomatous arteritis
Pulmonary artery involvement	No	Occasionally
Renal hypertension	Rare	Common
Claudication	Uncommon	Common
Ethnic groups with highest incidence	Scandinavians	Asians
Corticosteroid responsive	Yes	Yes
Bruits present	Minority	Majority
Surgical intervention needed	Rare	Common

Cogan's syndrome typically produces ocular inflammation (especially keratitis) and vestibuloauditory dysfunction. The one rheumatic disease that can be difficult to distinguish from TA is GCA (Table 88-14). Usually, the patient's age and the distribution of lesions allow their rapid differentiation, but distinguishing TA beginning after age 40 from GCA affecting chiefly the major branches of the aorta can be difficult or even impossible. The similarity of treatment (see later) diminishes the practical importance of solving this diagnostic dilemma.

Infections of the aorta are rare in most countries. Tertiary syphilis can be excluded by a negative fluorescent treponemal antibody test (the rapid plasma reagin test is falsely negative in about one-quarter of patients with late syphilis). Other diseases of the aorta (see Table 88-14) are usually readily separated from TA by the history and physical examination. There has been growing appreciation for a small subset of patients who have noninfectious aortitis that is difficult to categorize. At one center, noninfectious aortitis was found in 8% of patients undergoing resection of the ascending aorta.¹⁰⁰ Although nearly 70% had giant cells, only a minority neatly fit a diagnosis of TA or GCA. A fraction of the cases of thoracic or abdominal aortitis are caused by a recently recognized inflammatory condition known as IgG4-related disease (IgG4-RD) associated with high levels of IgG4.¹⁰¹

Treatment

Medical Therapy

Corticosteroids are the cornerstone of treatment of active TA.⁸⁹ Prednisone, at a dose of 0.5 to 1 mg/kg per day, is indicated for the treatment of active disease. Criteria for active disease include new onset or worsening of two or more of the following: (1) fever or other systemic features (in the absence of other cause); (2) elevated ESR; (3) symptoms or signs of vascular ischemia or inflammation (e.g., claudication, absent pulse, carotidynia); and (4) typical

angiographic lesions.⁸⁹ Although about 85% of TA patients present with active disease, about 15% do not.⁷⁴ The initial dose of prednisone is continued for 4 to 12 weeks before commencing a gradual taper, as is done when treating GCA (see earlier). Although nearly two-thirds of patients achieve remission, more than half later relapse. Relapses are especially common as the prednisone dose falls below 20 mg per day.

Relapses can be treated by increasing the prednisone dose or adding an immunosuppressive agent. No agent used for TA has been evaluated in a double-blind, placebo-controlled trial. However, open trials have suggested that weekly oral methotrexate (started at 0.3 mg/kg per week, with the initial dose not to exceed 15 mg/wk) is a moderately effective corticosteroid-sparing drug.¹⁰² Methotrexate can be gradually increased to 25 mg/wk. The emphasis is on lowering the corticosteroid dose because methotrexate seldom allows the elimination of prednisone completely; most patients continue to require at least 5 to 10 mg/day of prednisone. Small open trials have provided even more encouraging results about the effectiveness of anti-TNF inhibitors (etanercept and infliximab) in treating patients with refractory TA.¹⁰³ These trials emphasize that although these agents can treat TA, they rarely cure it: relapses are likely when the treatment is stopped.¹⁰³ Tocilizumab, which blocks the IL-6 receptor, has also been reported effective in individual patients.¹⁰⁴ Caution should be used when interpreting these results because similar open-label studies in GCA and PMR were also positive.

Small studies and series suggest that other corticosteroid-sparing drugs include azathioprine (2 mg/kg per day), mycophenolate mofetil (2000 mg/day), and cyclophosphamide (2 mg/kg per day).^{89,105} The toxicity of cyclophosphamide in young women is so high that it is rarely used in TA.⁸⁹

To prevent osteoporosis, patients on chronic corticosteroids should take calcium and vitamin D and perform weight-bearing exercises (see Table 88-8). In postmenopausal women, a bisphosphonate should be added if the bone mineral density is low (see Table 88-8). In premenopausal women, caution in use of bisphosphonates is advised: Their usefulness is less clear and recent use can harm a fetus. Modifiable risk factors for atherosclerosis—especially hypertension, smoking, inactivity, diabetes, and hyperlipidemia—should be treated maximally.

Surgical Therapy

TA is the form of vasculitis most frequently requiring revascularization procedures.^{89,106,107} Unfortunately, medical therapy rarely reduces or reverses stenotic lesions. Treating stenotic or aneurysmal lesions may require bypass surgery (especially of stenotic cervicobrachial arteries, coronary arteries, or renal arteries); aortic valve replacement (for aortic regurgitation); or percutaneous transluminal angioplasty (especially for stenotic renal arteries causing hypertension).

A review of the experience with vascular interventions in TA supports several general recommendations. First, the mere presence of stenosis does not necessitate intervention. The gut, for example, has such rich collaterals that even critical stenoses of the celiac, superior, or inferior mesenteric arteries usually produce no symptoms and require no

surgical intervention. Moreover, many patients with arm claudication will develop collateral circulation and improve substantially over time with medical therapy alone. For upper extremity vascular insufficiency, patiently waiting for a response to medical therapy usually pays higher dividends than undertaking rapid surgical intervention. Second, whenever possible, surgical intervention should be deferred until TA is in remission; procedures done during active disease often produce disappointing results. Third, bypass surgery yields better results than angioplasty. With bypass graft procedures, autologous vessels give better results than synthetic grafts (restenosis rates of 9% vs. 36%). Patients who undergo aortic surgery are liable to develop anastomotic aneurysms; such aneurysms developed in nearly 14% of patients followed for 20 years.^{106,108} Although angioplasty gives good short-term results, long-term results are often disappointing except for very short stenotic segments.¹⁰⁸ The experience with conventional stents has been mostly disappointing.

Outcome and Prognosis

Twenty percent of TA patients have a self-limited disease. The rest have a relapsing-remitting or progressive course requiring chronic corticosteroid and/or immunosuppressive therapy. Nearly two-thirds of patients experience new angiographic lesions. In one study from the National Institutes of Health, 74% of patients experienced some form of morbidity and 47% were permanently disabled.⁸⁹ In a Japanese study of 120 patients, survival at 15 years was 83%.¹⁰⁸ Age of onset older than 35 years; development of major complications (i.e., retinopathy, hypertension, aortic regurgitation, and aneurysm); or a progressive course was associated with decreased survival. Congestive heart failure and renal failure are the most common causes of death.¹⁰⁶ Pregnancy appears to be relatively well tolerated in the presence of good medical care and in the absence of abdominal aortic involvement.^{89,109}

KEY POINTS

Granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and allergic granulomatosis with polyangiitis (AGPA) are forms of vasculitis that affect small to medium-sized vessels and share a number of clinical, pathologic, and laboratory features.

Animal models, in vitro studies, and clinical studies support a pathogenic role for antineutrophil cytoplasm antibodies (ANCA) in most patients.

Testing for ANCAs and more specific autoantibodies by immunoassay is a useful tool in the diagnosis of small vessel vasculitis, but its role in disease monitoring is more controversial.

GPA can affect any organ or tissue but has a predilection for the upper and lower respiratory tracts and the kidneys. GPA is most commonly associated with ANCA positivity by immunofluorescence and positive testing for the proteinase-3 antigen.

MPA can be distinguished from other forms of small vessel vasculitis by the absence of granuloma formation and the predominance of perinuclear ANCA staining by immunofluorescence and positive testing for the myeloperoxidase antigen.

AGPA can be distinguished from other forms of small vessel vasculitis on the basis of a prior history of adult-onset asthma or allergic rhinitis and tissue eosinophilia with necrotizing vasculitis and extravascular granuloma formation.

Combination therapy with glucocorticoids and cyclophosphamide is required for the treatment of systemic small vessel vasculitis; methotrexate may be substituted for cyclophosphamide in non-organ-threatening disease. In those with severe disease, plasma exchange should be used as an adjuvant. Rituximab may be an alternative induction agent for those unable to receive cyclophosphamide. Patients with AGPA without any adverse prognostic signs may be treated with steroids alone.

Upon induction of disease remission, cyclophosphamide should be switched to less toxic immunosuppressive agents, such as azathioprine, for maintenance of remission.

With current therapeutic regimens, long-term outlook has improved, with 78% of patients surviving 5 years.

CLASSIFICATION OF THIS GROUP OF VASCULITIDES

(American College of Rheumatology [ACR] and European League Against Rheumatism [EULAR] Criteria for Disease)

Antineutrophil Cytoplasm Antibody–Associated Vasculitis

CAROLINE O.S. SAVAGE • LORRAINE HARPER

The primary systemic vasculitides involve small and medium-sized vessels and are associated with autoantibodies that target neutrophil cytoplasm antigens (antineutrophil cytoplasm antibodies [ANCAs]). Thus they are frequently referred to as ANCA-associated vasculitides (AAVs), although the terminology *ANCA disease* has also been proposed.¹ The presence of ANCA suggests that AAVs are autoimmune diseases. Individual disease descriptions include granulomatosis with polyangiitis (GPA), formerly known as Wegener's granulomatosis; microscopic polyangiitis (MPA); allergic granulomatosis with polyangiitis (AGPA), formerly known as Churg-Strauss syndrome; and renal-limited pauci-immune necrotizing and crescentic glomerulonephritis (RLV). The name changes have been recommended by the Boards of the ACR, the American Society of Nephrology, and EULAR, which wished a shift from eponyms to disease-descriptive or cause-based nomenclature.

The major autoantigens to which ANCAs are directed within neutrophils and monocytes include two enzyme proteins identified in the 1980s as autoantigens, namely, proteinase-3 (PR3), myeloperoxidase (MPO) (Figure 89-1), and, more recently, lysosome-associated membrane protein 2 (LAMP2).²⁻⁴ Confirmation of the presence of antibodies directed against LAMP2 in AAV is awaited, so this antibody subclass is not routinely tested for in current clinical practice.

The initial descriptions of GPA, MPA, and AGPA occurred in the 1930s, 1940s, and 1950s, respectively. However, the term *polyarteritis nodosa* (PAN) was often used during this period in a generic manner to cover these conditions, particularly MPA, despite the fact that Kussmaul and Meyer had clearly described PAN in 1866 as a systemic condition in which inflammation of medium-sized muscular arteries occurs, leading to aneurysm formation and ischemic tissue or organ infarction.⁵ The AAVs, in contrast, are generally considered disorders affecting both small and medium-sized arteries. In 1990, the ACR published classification criteria for seven types of vasculitis that included GPA and AGPA, but not MPA, thereby helping to begin to unravel the complexities of vasculitis classification. Four criteria were selected for GPA:

- Abnormal urinary sediment (red cell casts or greater than five red blood cells per high-power field)
- Abnormal findings on chest radiograph (nodules, cavities, or fixed infiltrates)
- Oral ulcers or nasal discharge
- Granulomatous inflammation on biopsy⁶

The presence of two or more of these four criteria was associated with a sensitivity of 88.2% and a specificity of 92%. It is worth bearing in mind that these criteria were

Figure 89-1 Immunofluorescence of diffuse or cytoplasmic antineutrophil cytoplasm antibody (c-ANCA; *left*), which is highly correlated with antibodies to proteinase-3 (PR3), and the less specific perinuclear pattern (p-ANCA; *right*), which is indicative of antibodies to myeloperoxidase (MPO). Although immunofluorescence was once the standard for ANCA testing, current standards require confirmatory antigen-specific testing for PR3 and MPO. (Courtesy Dr. C.G.M. Kallenberg.)

based on clinical features of 85 patients with GPA who were compared with 722 control patients with other forms of vasculitis.

Six criteria were selected for AGPA:

1. Asthma
2. Eosinophilia greater than 10% on differential blood cell count
3. Mononeuropathy (including multiplex) or polyneuropathy
4. Nonfixed pulmonary infiltrates on chest radiograph
5. Paranasal sinus abnormality
6. Biopsy containing a blood vessel with extravascular eosinophils⁷

The presence of four or more of these six criteria gave a sensitivity of 85% and a specificity of 99.7%. The criteria for AGPA were based on clinical findings in 20 patients compared with 787 controls with other forms of vasculitis.

The next major step forward was development of definitions for forms of vasculitis by the Chapel Hill Consensus Conference (CHCC) in 1994, which included GPA, MPA, and AGPA in the 10 types of vasculitis considered.⁸ These are shown in totality in [Table 89-1](#). Neither the ACR classification criteria nor the CHCC definitions included ANCA as a criterion. Lack of classification criteria for MPA prompted development of an algorithm by international consensus that has been validated in two separate populations, covering GPA, MPA, and AGPA, as well as PAN.^{9,10}

The ACR classification criteria and the CHCC definitions were not designed as diagnostic criteria. Indeed, the positive predictive value of the ACR classification criteria can be as low as 29% in clinical practice.¹¹ Although attempts have been made to develop diagnostic criteria based on the CHCC, these Sorensen criteria have not been validated.¹² Indeed, believing the ACR criteria for AGPA, PAN, and some other vasculitides, and the CHCC definitions for GPA, MPA, and PAN to no longer be fit for purpose, EULAR convened an expert consensus group to consider re-evaluating definitions, classifications, and diagnostic criteria in systemic vasculitis. Seventeen points to consider were formulated before the development of classification criteria and definitions in the systemic vasculitides that related to biopsy, laboratory testing, diagnostic radiology, nosology, definitions, and the research agenda.¹³ Not all of the points were relevant to AAV. Those that were relevant included the following:

- Histology point 1: Although histology is fundamental to the diagnosis of vasculitis and exclusion of its mimics, biopsy of affected organs is not always possible, and yields vary significantly according to conditions and target organs.
- Laboratory testing point 4: ANCA testing plays an important diagnostic role in suspected small vessel vasculitis.
- Diagnostic radiology point 10: Computed tomography (CT) and magnetic resonance imaging (MRI) may be useful in diagnosing ear, nose, and throat (ENT) involvement associated with GPA/AGPA.
- Nosology points 12 to 14: The nomenclature in use for distinguishing between “disease definitions,” “classification,” and “diagnostic” criteria is confusing and should be clarified wherever possible. Nosology of different forms of vasculitis should be a reflection of their etiopathogenesis, wherever this has been determined. In the absence of this, definition must rely on a clear, accurate description of the salient features of the condition. The use of eponyms should be reviewed if a more rational approach to nomenclature can be developed, based on etiopathogenesis, but their retention is necessary at present to avoid confusion.
- Definitions point 15: Age is worthy of inclusion in the definitions of some forms of vasculitis, but its role should not be overstated.
- Research agenda points 16 and 17: Future criteria initiatives should include all forms of vasculitis, providing definitions of less common syndromes not covered by CHCC. The development of a classification tree will provide the foundation for future criteria.

EPIDEMIOLOGY

Determining the incidence and prevalence of AAV is challenging given the uncommon occurrence of the disorders, difficulties in case ascertainment, the slow evolution of classification criteria and definitions fit for epidemiologic purposes, and the clinicopathologic overlaps that occur between the component diseases designated ANCA-associated diseases (GPA, MPA, AGPA) and their limited variants, including RLV. Most studies have been carried out in populations of European ancestry using data that were collected

Table 89-1 Classification of Vasculitis as Adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis*

	Histopathology	Comments
Large Vessel Vasculitis		
Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery	Often involves the temporal artery Usually occurs at >50 yr of age Often associated with polymyalgia rheumatica
Takayasu's arteritis	Granulomatous inflammation of the aorta and its major branches	Usually occurs at <50 yr of age
Medium-Sized Vessel Vasculitis		
Polyarteritis nodosa [†] (classic polyarteritis nodosa)	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules	
Kawasaki disease	Arteritis involving large, medium-sized, and small arteries, associated with mucocutaneous lymph node syndrome	Coronary arteries often involved Aorta and veins may be involved Usually occurs in children
Small Vessel Vasculitis		
Granulomatosis with polyangiitis [‡]	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels (capillaries, venules, arterioles, arteries)	Necrotizing glomerulonephritis common
Allergic granulomatosis with polyangiitis [‡]	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels, associated with asthma and blood eosinophilia	
Microscopic polyangiitis [‡]	Necrotizing vasculitis with few or no immune deposits affecting small vessels (capillaries, venules, arterioles)	Necrotizing arteritis involving small and medium-sized arteries may be present Necrotizing glomerulonephritis very common Pulmonary capillaritis often occurs
Henoch-Schönlein purpura	Vasculitis with IgA-dominant immune deposits affecting small vessels (capillaries, venules, arterioles)	Typically involves skin, gut, and glomeruli Associated with arthralgia or arthritis
Essential cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (capillaries, venules, arterioles) and associated with cryoglobulins in serum	Skin and glomeruli often involved
Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis	

*Large arteries include the aorta and the largest branches directed toward major body regions (e.g., the extremities, head and neck). Medium-sized arteries are the main visceral arteries (e.g., renal, hepatic, coronary, mesenteric). Small arteries are distal arterial radicles that connect with arterioles. Note that some small and large vessel vasculitides may involve medium-sized arteries, but large and medium-sized vessel vasculitides do not involve vessels smaller than arteries.

[†]Preferred term.

[‡]Strongly associated with antineutrophil cytoplasm antibodies.

retrospectively. Despite these difficulties, collective studies suggest that the AAVs have an incidence of around 10 to 20 per million and prevalence rates that have been increasing over the past two decades (summarized in Reference 14). The peak age of onset is 65 to 74 years; the disease is very rare in childhood, and most studies suggest a slightly higher occurrence in men than in women (1.5:1.0).

Within the spectrum of ANCA-associated disease are interesting geographic and population differences in the relative incidence of GPA versus MPA or AGPA, or between MPO-ANCA and PR3-ANCA positivity. In populations of European ancestry, GPA appears to have an incidence of around 2 to 10 per million, depending on the geographic location, with the higher 8 to 10 per million incidence being reported in more northerly countries and lower incidences of 3 to 6.6 per million in Greece and Spain.¹⁵⁻¹⁷ A similar inverse relationship between GPA and MPA has been observed in the southern hemisphere,¹⁸ and a possible link to ultraviolet exposure has been proposed.¹⁹

However, in a Japanese population studied for occurrence of primary renal vasculitis, more than 90% had MPO-ANCA, but PR3-ANCA was not observed, and neither GPA nor AGPA was diagnosed clinically.²⁰ In China, MPA also seems to be more common than GPA¹⁰; high rates of MPA have also been reported in a Peruvian population and in Kuwait, where the incidence of MPA was reported as 24 per million.^{21,22}

Considering epidemiologic studies for GPA in greater detail, studies from Finland, Norway, and Sweden have suggested an increased incidence over the past two to three decades,²³⁻²⁵ but others from Germany and the United Kingdom and a later Swedish study have not.²⁶⁻²⁸ Overall, it is most likely that methodological factors account for reported differences, with no significant increase in incidence occurring during the past two decades. Prevalence figures for GPA have been increasing, which probably reflects improved treatment regimens. In a primary care-based population in the United Kingdom, the prevalence

increased from 28.8 per million in 1990 to 64.8 per million in 2005.¹⁵ Prevalence figures are now available for several populations in Europe, the United States, and the southern hemisphere over various time periods (summarized in Reference 14).

Epidemiologic studies in MPA have variously shown an increased incidence or not over the past two decades. It is possible that earlier suggestions of an increased incidence reflected increasing awareness of MPA and its differentiation from PAN and GPA. An interesting increase in cases of MPA in Japan followed the Kobe earthquake in 1995.²⁹

AGPA is the least common of the AAVs, with an incidence around 1.0 to 3.0 per million, although this increases in patients with asthma to 34.6 per million person-years.³⁰ AGPA affects a similar age of population as GPA and MPA, but its occurrence is more common in women than in men. An association has been noted between the development of AGPA and the administration of leukotriene inhibitors or the anti-immunoglobulin (Ig)E monoclonal antibody omalizumab, possibly due to unmasking of previously unrecognized disease with reduction of corticosteroid dose.^{31,32}

Environmental factors are relevant to AAV.³³ There appears to be a higher incidence of GPA in rural as compared with urban areas.³⁴ No clear seasonal variation trends have been identified. Infection as a trigger for autoimmune disease in general, and for AAV in particular, is often hypothesized. The closest association is between *Staphylococcus aureus* and GPA, with nasal carriage of *S. aureus* being linked to a higher incidence of disease relapse.³⁵ Silica exposure has been linked to AAV in several studies, including a case-control study in the United States.³⁶ Exposure to several drugs, including propylthiouracil, has also been associated with AAV.³⁷ Cocaine abuse has been linked to a midline destructive granulomatous disease that mimics GPA.³⁸

GENETICS

Evidence of a heritable risk for AAV comes from recent studies suggesting a modestly increased risk of disease in first-degree relatives,³⁹ similar to that found in rheumatoid arthritis (RA). Children of patients with GPA have an increased risk of RA,⁴⁰ suggesting familial clustering of genes associated with inflammatory autoimmune disease. Occasional familial cases of GPA are also reported in the literature.^{41,42} Given the relatively modest risk of disease in family members, it is likely that several genes contribute a small effect on disease development. Undertaking genetic studies in AAV is challenging owing to the rarity of the disease as the statistical power of genetic association studies is determined by the number of cases and controls included in the analysis. A number of candidate genes, often involving the immune response, have been identified. However, many association studies have produced inconsistent results because of the small number of cases studied. More recent studies have used larger numbers of patients with evidence of validation of results by duplication in separate cohorts of patients. Large cohorts of patients are being assembled to allow performance of genome-wide association studies, in which thousands of genes across the genome are compared.

Consistent genetic associations with multiple autoimmune conditions have been restricted to three gene regions: human leukocyte antigen (HLA) class II region, CTLA4, and the *PTPN22* gene. HLA genes are exceedingly polymorphic, and small studies suggest associations between GPA and HLA compared with healthy controls. However, most of these studies are of poor reliability because of their small size and lack of replication in independent cohorts. Recently, a larger study of 150 German patients with GPA identified an association with the HLA-DPB1*0401 allele. In contrast, the *0301 allele frequency was significantly decreased.⁴³ The extended haplotype DPB1*0401/RXB03 showed stronger association, suggesting that this genomic region confers significant risk for development of GPA. Among other functions, the retinoid X receptor β protein forms heterodimers with vitamin D receptors. Vitamin D receptor is important for the effects of the active vitamin D metabolite 1,25-dihydroxycholecalciferol. Active vitamin D has potent immunomodulatory properties, which include inhibition of cytokine transcription and differentiation of T cells toward a T regulatory (Treg) cell phenotype.⁴⁴ This association has been replicated in a larger cohort of 282 GPA patients.⁴⁵ The association with *0401 was present only in ANCA-positive GPA patients. Other studies have shown associations with HLA-DR. A relatively large study (304 AAV patients and 9872 controls) has shown associations with HLA-DR4,⁴⁶ and another showed that HLA-DRB1*04 was increased in frequency in GPA patients with end-stage renal failure.⁴⁷

Different HLA associations have been found in AGPA with disease associating with HLA-DRB4 alleles, while HLA-DRB3 afforded disease protection.⁴⁸ No association of AGPA with HLA-DPB has been described.⁴⁹ Different HLA associations suggest that AGPA and GPA may be different disease entities despite many similarities. This is supported by observations that showed association of the extended IL-10.2 haplotype with ANCA-negative AGPA but not GPA.⁴⁹

Cytotoxic T lymphocyte-associated antigen 4 (CTLA4) is expressed mainly on activated CD4⁺ T cells and inhibits T cell function. Polymorphisms in the *CTLA4* gene have been associated with several autoimmune diseases.⁵⁰ Several studies have shown associations with polymorphisms in the *CTLA4* gene. The most widely implicated *CTLA4* polymorphism for risk of autoimmunity is the +49 single nucleotide polymorphism (SNP) (alanine-to-threonine substitution in the leader peptide), which appears to affect cell surface expression of CTLA4 in response to T cell activation.^{51,52} The CT60 SNP appears to affect the expression of soluble CTLA4 and to alter the signaling threshold of CD4⁺ T cells.⁵³ Both of these SNPs have been associated with disease in patients with AAV.⁵⁴⁻⁵⁷

PTPN22 encodes the lymphoid tyrosine phosphatase LYP, which forms a complex with the kinase Csk and is a critical negative regulator of signaling through the T cell receptor. The R620W variation, which has been associated with autoimmunity, disrupts the interaction between Lck and LYP, leading to reduced phosphorylation of LYP, which ultimately contributes to gain-of-function inhibition of T cell signaling.⁵⁸ Two studies have shown an association of the *PTPN22* 620W allele with AAV,^{57,59} suggesting that this

is likely to contribute to the risk of AAV, as in other autoantibody-associated autoimmune diseases.

Numerous other candidate genes have been investigated in patients with AAV. Alpha1 antitrypsin (A1AT) is the major inhibitor of PR3. The A1AT gene is highly polymorphic. The deficiency alleles S and Z are increased in patients with AAV.⁶⁰⁻⁶³ However, most individuals with A1AT homozygous for the Z allele do not develop AAV.⁶⁴

PR3 is expressed on the membrane of neutrophils and appears to be genetically determined.⁶⁵ Patients with GPA tend to have higher percentages of neutrophils expressing PR3 than healthy controls,⁶⁶ particularly those with relapsing disease.⁶⁷ However, increased expression does not appear related to 564 promoter polymorphism of the PR3 gene.^{68,69} The percentage of neutrophils expressing PR3 may be influenced by HLA antigens, although the mechanism of this is unclear. In one study, a group of 34 HLA antigens was found to predict 64% of the variability in PR3 membrane expression.⁷⁰ This study requires replication in an independent cohort of patients. Less support has been found for a genetic association affecting the expression of MPO. A recent meta-analysis showed no association with the functional promoter polymorphism (G-463A) in the MPO gene.⁷¹

Many other genes have been investigated, but results are conflicting owing to the small size of the studies and require further investigation. However, it is clear that existing studies suggest a complex model of genetic variability. Future studies need collaboration between groups to increase the number of available cases of these rare diseases.

CLINICAL FEATURES

The three types of AAV may all be associated with marked constitutional upset comprising fevers, night sweats, myalgia, and arthralgia. Systemic vasculitis may also lead to certain commonality of features that may occur in some, but not all, patients. Thus nail-fold hemorrhages, purpuric rashes, and cutaneous ulcers may be observed.

Microscopic Polyangiitis

The first descriptions of MPA were provided in 1948 by Davson, Ball, and Platt, who described an illness that they termed *microscopic polyarteritis*, distinguishing it from polyarteritis nodosa by its marked segmental necrotizing glomerulonephritis and greater propensity to involve small vessels.⁷²

The pathology of MPA is of a fibrinoid necrotizing vasculitis with few or no immune deposits that primarily affects small vessels such as capillaries, arterioles, or venules, although spread to include small and medium-sized arteries may occur. A focal segmental necrotizing glomerulonephritis is very common and may progress into a full blown crescentic glomerulonephritis.⁷³ However, in view of the sometimes indolent nature of the disease, evidence of chronic damage with obsolete glomeruli and tubulointerstitial fibrosis may be present at the time of the first diagnostic kidney biopsy.⁷⁴ Examination of the kidney by immunohistology or electron microscopy reveals few or no immune deposits, although careful inspection may indicate that some complement fragments are present.⁷⁵ Within the

lungs, a pulmonary capillaritis may develop, and, following rupture of capillaries, blood can spill into alveolar spaces and thrombosis may occur within capillaries themselves. Marked neutrophilic infiltration of the alveolar wall is usually seen; this ultimately undergoes fibrinoid necrosis. Type II epithelial cell hyperplasia and lymphoplasmacytic infiltration can develop.

The pathophysiologic understanding of MPA advanced considerably after the strong association between MPA and ANCA was recognized, particularly ANCA directed toward myeloperoxidase (MPO).^{2,76} A small percentage of patients have ANCA directed toward proteinase-3 (PR3). ANCAs are believed to bind to their target antigen on the surface of primed neutrophils, leading to further neutrophil activation with release of proinflammatory granule contents and reactive oxygen species, as well as increasing adherence and damage to endothelial cells (Figure 89-2) (reviewed in Reference 77). Studies in mouse and rat species have provided direct evidence that anti-MPO antibodies induce systemic vasculitis, including necrotizing glomerulonephritis,^{78,79} and can promote neutrophil-endothelial cell interactions *in vivo*.^{80,81}

The clinical features of MPA have been recognized for many years⁸²⁻⁸⁵ and are summarized in Table 89-2. The most commonly affected organs are the kidneys and the lungs. Symptoms can involve the ears, nose, or throat, but distinction from GPA then needs to be considered. The presentation can be insidious with symptoms of deteriorating renal function on the background of mild features that can be attributed to a low-grade vasculitis; alternatively, it may be severe and acute with rapidly progressive glomerulonephritis and pulmonary hemorrhage, presenting as a pulmonary renal syndrome; or it may appear to be limited to the kidney, sometimes being described as renal-limited vasculitis.

Renal manifestations include microscopic hematuria, an abnormal renal sediment with red cell casts, proteinuria that is not usually of nephrotoxic proportions (i.e., is less than 3.5 g per 24 hours), and variable loss of kidney function. The presence of red cell casts is always indicative of an active glomerulonephritis, and the presence of red cells in a patient with long-standing disease may be due to active disease or to damage in the absence of disease activity, or indeed to other conditions affecting the lower urinary tract, including cystitis or bladder malignancy, as a result of cyclophosphamide therapy.⁸⁶ Loss of renal function can be very rapid, occurring over days or weeks. Dialysis may be required,

Table 89-2 Principal Clinical Features of Microscopic Polyangiitis

Clinical Feature	Percentage*
Constitutional symptoms	76-79
Fever	50-72

*Percentage of a population totaling 150 patients from four studies.⁸²⁻⁸⁵

Figure 89-2 Schematic representation of the immune mechanisms hypothetically involved with antineutrophil cytoplasm antibody (ANCA) enhancement of vascular injury. An infectious trigger or another environmental stimulus leads to a burst of cytokines, which prime the neutrophils or monocytes, possibly leading to local upregulation of adhesion molecules on endothelium. The priming process within the inflammatory cells leads to enhanced expression of ANCA antigens on the cell surface. Activated neutrophils or monocytes may degranulate and release reactive oxygen species (O^-) and lysosomal enzymes, leading to endothelial injury and further activation of the endothelial cell surface. The magnitude of this effect is influenced by the specificity of ANCA for proteinase-3 (PR3) or myeloperoxidase (MPO), as well as different epitopes of these respective antigens. The reaction may be further influenced by the immunoglobulin G (IgG) and Fcγ receptor phenotype engaged. Products released from degranulated inflammatory cells become bound to endothelial cells and further serve as targets of ANCA. Release of chemotactic chemokines such as interleukin-8 (IL-8) and macrophage chemoattractant protein-1 (MCP-1), in conjunction with other adhesion molecules, serves to augment chemotaxis and inflammatory cell transmigration. Thus, the scheme provides the prerequisites for endothelial and vascular injury induced by ANCA, that is, the presence of ANCA, expression of target antigens for ANCA on primed neutrophils and monocytes, interaction between primed neutrophils and endothelium via adhesion molecules, and finally, activation of endothelial cells and ultimate efflux of inflammatory cells to extravascular and perivascular tissues. FcγR, Fcγ receptor; ICAM-1, intercellular adhesion molecule-1; PMN, polymorphonuclear leukocyte; TNF, tumor necrosis factor.

but some recovery of renal function may occur following treatment. In patients who remain on dialysis, the likelihood of relapse is less than before dialysis, so the need for immunosuppression may be less.⁸⁷ Although kidney involvement is present in most patients, it is not invariable.

Lung involvement occurs in up to a third of patients.⁸²⁻⁸⁵ Clinical features include cough, dyspnea, pleurisy, and hemoptysis. Onset may be insidious or acute and severe. Widespread pulmonary hemorrhage can occur without overt hemoptysis. Chest radiograph findings may be patchy or diffuse, reflecting alveolar infiltrates. Repeated episodes of lung hemorrhage can lead to pulmonary fibrosis.

Granulomatosis with Polyangiitis

GPA is a granulomatous disorder, often associated with fibrinoid necrotizing vasculitis, which was first described in 1931 by Klinger,⁸⁸ with pathologic refinement added to the description by Wegener in 1936.⁸⁹

The pathology of GPA comprises granulomas and necrosis, as well as the vasculitis, which is similar to that occurring in MPA.⁷³ Pathologic biopsy material is taken more frequently from the nasal mucosa, lung, skin, or kidney. All features are not usually present in any one biopsy specimen, given the small sample of material that may be available, so findings may be compatible with the diagnosis but not diagnostic. In the lung, open biopsies generally are more likely

to be diagnostic than transbronchial biopsies.^{90,91} Renal pathology is similar between MPA and GPA, and granulomas are rarely seen in the kidney (Figure 89-3); sometimes intense periglomerular leukocytic infiltration has the appearance of pseudogranulomas.⁹²

The pathophysiology of GPA, as with MPA, is believed to be inherently autoimmune⁹³ and driven by PR3-ANCA in a manner very similar to that proposed for MPO-ANCA,⁷⁷ with PR3-ANCA being highly specific for GPA.^{76,94} However, a good animal model is not available for anti-PR3 antibodies, so direct evidence for a role in development of vasculitis, or indeed in granuloma formation, is not available as with anti-MPO antibodies; this may reflect differences in expression of PR3 on murine neutrophils. However, the *ex vivo* effects of MPO-ANCA and PR3-ANCA on human neutrophils are very similar (reviewed in Reference 77). B cells and T cells are also acknowledged to play important roles in the AAV diseases, with recent demonstration of responsiveness to anti-B cell therapies placing increased interest in the role that B cells play.^{95,96} T cell subset abnormalities have repeatedly been described in MPA and GPA, but the nature of the factors responsible for these changes has not been defined.

The clinical features of GPA are driven by a predilection for the upper and lower respiratory tracts, as well as for the kidneys. GPA may occur as a disease limited to the respiratory tract without evidence of systemic involvement, when

Figure 89-3 Antineutrophil cytoplasm antibody–associated crescentic glomerulonephritis. This toluidine blue–stained plastic section demonstrates a glomerulus with a cellular crescent. Bowman's space is partially obliterated by a proliferation of epithelial cells and macrophages. All types of crescentic glomerulonephritis appear similar by light microscopy, and immunofluorescence is needed to distinguish among pauci-immune, immune complex, and anti-glomerular basement membrane subtypes. (Courtesy Dr. J. Myles.)

it is referred to as limited GPA; such presentation is usually as a granulomatous disorder without vasculitic features. In a recent study, 10% of patients evolved to develop generalized disease within a median time of 6 years.⁹⁷ Upper airway disease is the most common presenting feature of GPA, occurring in more than 70% and eventually being present in more than 90% of patients.^{90,98} Serous otitis media and conductive and sensorineural hearing loss may occur; vertigo is rare. Nasal involvement causes mucosal swelling with obstruction, crusting, septal perforations, serosanguinous discharge, and epistaxis; a saddle nose deformity due to collapse of the cartilaginous portion of the nasal septum may develop (Figure 89-4). Sinusitis is common and will occur in more than 80% at some point during the illness (Figure 89-5)⁹⁹; bony erosion may develop and can be

Figure 89-4 Saddle-nose deformity in a patient with granulomatosis with polyangiitis. (Courtesy Dr. G. Hoffman.)

Figure 89-5 Computed tomography scan of the sinuses, revealing the presence of chronic sinusitis.

detected better using CT scanning of the sinuses than by plain radiography. *S. aureus* may infect sinuses and is commonly carried on the diseased nasal mucosa, where it may be one factor contributing to disease relapse.³⁵ Laryngotracheal disease may cause hoarseness but may also progress to severe stridor and upper airway obstruction, usually following subglottic stenosis (Figure 89-6). Direct laryngoscopy may reveal an ulcerated friable mucosa, and tracheal tomograms, CT, or MRI can help to further delineate the extent of the stenosis. In occasional patients, subglottic stenosis can precede the development of other features of the disease by years; in others, subglottic stenosis may develop despite apparently effective control of the disease.

Pulmonary involvement will affect around 90% of patients at some point during the course of disease.⁹⁰ Symptoms are similar to those associated with MPA, although some patients may have asymptomatic disease that is detected only after imaging. In addition to the capillaritis (Figure 89-7) and vasculitis that occur in MPA, patients with GPA are burdened with granulomatous disease that causes development of nodules of chronic granulation tissue

Figure 89-6 Subglottic stenosis in a patient with granulomatosis with polyangiitis. Magnetic resonance imaging (left) and endoscopic view (right). (Right, Courtesy Dr. G.S. Hoffman; from Hoffman GS, Kerr GS, Leavitt RY, et al: *Wegener granulomatosis: an analysis of 158 patients*, Ann Intern Med 116:488–498, 1992.)

Figure 89-7 Capillaritis. Alveolar septa with congestion, neutrophilic infiltrate, and fibrinoid necrosis of capillary walls. Adjacent alveolar spaces contain hemosiderin-laden macrophages, consistent with a history of pulmonary hemorrhage (hematoxylin and eosin, $\times 40$). (Courtesy Dr. C. Farver.)

that can cavitate centrally.¹⁰⁰ The most common radiographic findings are pulmonary infiltrates and nodules (Figure 89-8). Infiltrates may be fleeting in nature but may be extensive, particularly when associated with severe pulmonary hemorrhage. Small nodules that are not apparent radiologically may be detected by CT scanning. Imaging may also demonstrate pleural effusion and mediastinal or hilar lymph node enlargement. Infection may be superimposed on the disease background; it is important to exclude this by culture and by bronchoscopy if necessary.¹⁰¹ If pulmonary hemorrhage is recent, the carbon monoxide diffusion capacity may be reduced if a patient is well enough to

allow the test to be undertaken. Depending on the progress of the disease, pulmonary function tests may show an obstructive or a restrictive component, particularly if fibrosis has developed following repeated episodes of hemorrhage or cyclophosphamide-induced pneumonitis.¹⁰²

The features of renal involvement in systemic GPA are similar clinically and pathologically to those in MPA. Renal involvement probably occurs in around 80% of patients at some time during the course of the illness,^{90,99} although determining the precise frequency overall is difficult. However, it should never be assumed that limited disease excludes the future development of renal and systemic disease because, as already noted, a proportion of patients will develop systemic disease at some point.⁹⁷ The lower urinary tract may also be affected with necrotizing vasculitis of the bladder, necrotizing urethritis, orchitis, epididymitis, prostatitis, and penile necrosis (reviewed in Reference 103). Urinary obstruction may develop, particularly with involvement of the ureters. Cystoscopy should be undertaken if unexplained persistent hematuria is present, to exclude bladder malignancy or other complications.

The eye may be affected in several ways during the course of GPA in 28% to 58% of patients.^{104,105} Keratitis, conjunctivitis, episcleritis, scleritis, uveitis, retrobulbar granulomatous disease with proptosis, ocular palsies, lacrimal duct obstruction, optic neuritis, and retinal vascular occlusion may all occur.¹⁰⁴⁻¹⁰⁶ Proptosis and optic neuritis are feared because they are particularly likely to lead to visual loss. Both CT and MRI may be helpful in defining retrobulbar disease (Figure 89-9). In patients treated with high doses of corticosteroids, cataracts may occur as a complication.

Both the peripheral and the central neurologic system can be affected in GPA.¹⁰⁷ Peripheral neuropathy may manifest as a mononeuritis multiplex or, less commonly, as a distal and symmetric polyneuropathy. Nerve conduction

Figure 89-8 Computed tomography scan of the lungs, revealing the presence of nodules. The right-sided pulmonary nodule is cavitary.

Figure 89-9 Computed tomography scan of the orbits, revealing the presence of a retro-orbital mass (orbital pseudotumor).

studies may be helpful in verifying the presence and extent of neuropathy, and biopsy of a nerve, usually the sural nerve, may establish the presence of vasculitis. Central nervous system disease occurs in a minority of patients—around 10%—but can be severe, particularly when a cerebral vasculitis is present.¹⁰⁸ Chronic pachymeningitis, cerebral hemorrhage and thrombosis, pituitary involvement, cerebral nerve involvement, brain stem lesions, spinal cord involvement, and subarachnoid or subdural hemorrhage may occur. Substantiating the presence of cerebral vasculitis may be difficult because small vessels are affected and angiography is of little utility. However, CT and MRI may help to define infarctions, hemorrhages, mass lesions, meningeal involvement, and white matter changes (Figure 89-10). Lumbar puncture may be necessary if subarachnoid hemorrhage is suspected or to exclude the presence of meningeal infection.

Cardiac involvement through coronary artery vasculitis and involvement of the myocardium by granulomatous disease may occur, and magnetic resonance angiography and

contrast-enhanced MRI may be useful in its detection.¹⁰⁹ Increased risk of cardiovascular disease is noted in patients with AAV, including GPA.^{110,111}

Symptomatic involvement of the gastrointestinal tract is not usually a major feature of GPA, or indeed of MPA. However, abdominal pain, bleeding, and diarrhea can occur as a result of the disease itself or through the effects of treatment, for example, corticosteroids can cause peptic ulceration and mycophenolate mofetil may cause diarrhea. The vasculitic process itself may lead to ulcerations, or even perforations, in the small or large intestine. A number of unusual presentations include involvement of the tongue and salivary glands (parotid, sublingual, or submandibular),¹¹² pancreatic involvement that may mimic pancreatic cancer,¹¹³ and cholecystitis and hepatic granulomatous disease that can cause liver failure.¹¹⁴ Splenic involvement with vasculitis, granulomas, and necrosis is present in many patients in older autopsy series.¹¹⁵

Allergic Granulomatosis with Polyangiitis

This syndrome was described by Churg and Strauss in 1951.¹¹⁶ It has three salient histopathologic features, namely, necrotizing vasculitis, tissue infiltration by eosinophils, and extravascular granulomas (Figure 89-11). To improve recognition of this disorder, Lanham suggested that diagnosis be based on clinical features comprising asthma, peak eosinophil count greater than 1500 cells/mL, and systemic vasculitis involving two or more organs.^{117,118} None of these clinical or pathologic features is entirely specific for AGPA, and they may not all be present or detectable concurrently.

The pathogenesis of AGPA is unknown, but a strong association has been noted with allergy and atopic disorders, including allergic rhinitis, nasal polyposis, and asthma. Around 70% of patients have elevated IgE levels,¹¹⁷ as well as eosinophilia of peripheral blood and tissue. The association with leukotriene inhibitors was described in the epidemiology section. Although ANCAs may be present and, if so, usually are directed to MPO, up to 60% of patients may be negative for ANCA.^{119,120} ANCA positivity is suggested to be associated with a higher incidence of renal disease, alveolar hemorrhage, mononeuritis multiplex, and purpura.^{119,120}

In some patients, AGPA appears to unfold in distinct phases: a prodrome with allergic features, followed by the vasculitic phase, and then dominance of the clinical picture by allergic disease.¹¹⁷ Asthma with pulmonary infiltrates on radiologic examination is typical, and infiltrates may have a lobar, interstitial, or nodular appearance. Pulmonary effusions can develop with eosinophils in the pleural fluid. Alveolar hemorrhage is a serious complication, as it is in other AAVs. Peripheral neuropathy occurs in around two-thirds of patients, taking the form of a mononeuritis multiplex with symmetric or asymmetric polyneuropathy. Cranial nerves can be affected, and occasionally central nervous system (CNS) disease develops. AGPA can affect the kidney, but less commonly than with MPA and GPA; the pathophysiology is similar, albeit with the presence of eosinophils. Lower urinary tract involvement may occur. As with other forms of AAV, multiple other organs can be affected occasionally, including the heart, gastrointestinal tract, and eye. Arthralgia and skin disease also occur as in other AAVs, although in AGPA, inflammatory skin nodules with the characteristic histopathology can develop. Features associated with a less favorable prognosis include creatinemia (>140 mmol/L [1.58 mg/dL]), proteinuria (>1 g/day), or central nervous system, gastrointestinal, or myocardial involvement according to the Five Factor Score developed by Guillevin and colleagues.¹²¹

DIAGNOSIS AND DIAGNOSTIC TESTS

Diagnosis depends on clinical recognition of potentially vasculitic or granulomatous disease patterns, backed up by histology, serology, and appropriate imaging tests.

A broad summary of factors that aid differential diagnosis between AAVs is given in Table 89-3.

Whenever possible, diagnosis should be confirmed by pathologic examination of affected tissues; for MPA, this is usually done via biopsy of kidney, lung, or skin; for GPA, nasal or paranasal mucosal biopsy may be helpful also, although such biopsies are usually “consistent with” rather than “diagnostic of” GPA, because vasculitis, necrosis, and granulomas are encountered together in only a minority of cases; for AGPA, biopsy of nerve or muscle may be helpful if those tissues are involved clinically. Confirmation of diagnosis by histology gives confidence to embarking on a course of therapy that may have serious adverse effects. In the case of the kidney, the biopsy may also yield some prognostic information, depending on the percentage of normal glomeruli present.¹²² Histologic classification of renal lesions into focal, crescentic, mixed, and sclerotic has been proposed to aid prognostic evaluation.¹²³

Laboratory results may confirm the presence of an acute phase response, define the nature and extent of individual organ involvement, or contribute to diagnostic evaluation through detection or not of a range of immune antibody products. Leukocytosis, normocytic normochromic anemia, thrombocytosis, and elevated erythrocyte sedimentation rate and C-reactive protein may be indicative of an acute inflammatory state. In AGPA, peripheral eosinophilia in excess of 1500 cells/mL is often present, although occasional patients may have marked tissue eosinophilia without blood eosinophilia.

Detection of PR3- and MPO-ANCA now occurs by antigen-specific enzyme-linked immunosorbent assay (ELISA), widely available as routine laboratory testing. As a screening assay, indirect immunofluorescence (IIF) using ethanol-fixed human neutrophils reveals two major staining patterns of antibody binding to neutrophils comprising a cytoplasmic pattern (cANCA) and a perinuclear pattern (pANCA) (see Figure 89-1). The cANCA pattern usually equates to specificity for PR3-ANCA, and pANCA usually equates to MPO-ANCA. Guidelines for testing for ANCA have been agreed by international consensus,¹²⁴ and if these guidelines are adhered to, the chance of missing a case of AAV are low while indiscriminant testing is avoided.¹²⁵ The combination of IIF and ELISA testing increases specificity.⁷⁶ Thus, when the IIF test was combined with ELISA testing

Table 89-3 Differential Diagnostic Features of the Antineutrophil Cytoplasm Antibody–Associated Vasculitides

Feature	Microscopic Polyangiitis	GPA	AGPA	Comments
Glomerulonephritis	+++	+++	+	Progressive renal failure uncommon in AGPA
Pulmonary infiltrates or nodules	++	+++	+++	Asthma and eosinophilia in AGPA
Alveolar hemorrhage	++	++	+	
Upper airway disease	+	+++	++	Ear, nose, and throat disease usually favors GPA
Skin, purpura	+++	+	++	
Peripheral nerve involvement	+	++	+++	Often a prominent feature of AGPA
Central nervous system involvement	+	+	+	

+++ , very commonly seen; ++ , seen often; + , uncommon finding; AGPA, allergic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis.

(cANCA/anti-PR3 positive, pANCA/anti-MPO positive), diagnostic specificity increased to 99%. The sensitivity of the combination of cANCA plus anti-PR3 or pANCA plus anti-MPO for GPA or MPA was 73% and 67%, respectively. The question of the status of ANCA-negative patients arises also because around 10% of patients may be negative; the reasons for this may include low titer antibody levels, a poorly performing IIF or ELISA test, or genuinely ANCA-negative disease. However, if clinical and pathologic features are consistent with AAV, patients generally should be treated along similar lines.

Both at the initiation of therapy and during monitoring, a number of tools are available to measure the extent of disease activity and the damage caused through effects of disease or treatment. Chief among these following their validation and use in multicenter randomized prospective clinical trials are the Birmingham Vasculitis Activity Score (now in its third iteration) and the Vasculitis Damage Index.¹²⁶⁻¹²⁸ Other outcome measures include the Five Factor Score (FFS) and the Disease Extent Index (reviewed in Reference 129).

TREATMENT

The natural history of untreated AAV is rapidly progressive and usually fatal, with a 2-year mortality of 85%. The introduction of cyclophosphamide-based regimens to treat AAV in the 1970s has dramatically improved patient survival to around 80% at 5 years.¹³⁰ The aim of treatment is to induce and then maintain disease remission and prevent relapse, using agents with the lowest adverse event profile.

Treatment is tailored according to the disease severity at presentation, and more aggressive immunosuppression is required in the presence of life- or organ-threatening disease.¹³¹ An algorithm for therapy is shown in Figure 89-12.

Induction of Remission

Cyclophosphamide, an alkylating immunosuppressant agent, with glucocorticoids is considered the “standard of care” as induction therapy for those with generalized disease.¹³² Treatment should be continued for 3 to 6 months with remission rates following induction treatment varying from 35% to 93% in GPA and from 75% to 89% in MPA.¹³³ Cyclophosphamide treatment is not without its complications. As with all immunosuppression, risk of infection is present. Other adverse events associated with cyclophosphamide in patients with GPA have included hemorrhagic cystitis, bladder cancer, bone marrow suppression, lymphoma, myelodysplasia, and infertility.^{86,90} A dose-response relationship between cyclophosphamide and the risk of bladder cancer has been demonstrated,¹³⁴ suggesting the need to treat with the lowest possible cumulative dose. There is therefore a need to balance the toxicity of treatment with the morbidity and mortality associated with disease.

One approach to limiting the cumulative cyclophosphamide dose has involved the use of pulsed cyclophosphamide versus the more traditional continuous daily regimens. A meta-analysis of three small, randomized studies suggested that pulsed intravenous cyclophosphamide was preferable

to daily oral cyclophosphamide in terms of remission and reduced adverse events.¹³⁵ A more recent randomized controlled trial in 149 patients with generalized disease performed by the European Vasculitis Study Group (EUVAS) showed no statistically significant difference in the time to remission or in the proportion of patients attaining remission at 9 months between those randomized to pulse cyclophosphamide compared with daily oral cyclophosphamide, despite an absolute lower cumulative dose of cyclophosphamide that was associated with a lower rate of leukopenia in the pulsed limb. This study did not have sufficient duration of follow-up and was not powered to detect a difference in relapse rates.¹³⁶

Other immunosuppressants may be used as alternatives to cyclophosphamide. Rituximab, an anti-CD20 chimeric monoclonal antibody that depletes B cells, has been shown to be effective in inducing remission in AAV in two randomized controlled trials. RITUXVAS compared cyclophosphamide- and rituximab-based regimens in newly diagnosed patients with severe AAV; the median glomerular filtration rate (GFR) at entry was 18 mL/min.¹³⁷ Forty-four patients were randomly assigned to receive two pulses of cyclophosphamide and four of rituximab or six to ten pulses of cyclophosphamide. Both groups received the same prednisolone dose and were followed for a minimum of 12 months. At 12 months, no differences were noted between the two groups in terms of remission rates, times to remission, or severe adverse events. The RAVE trial also supports the use of rituximab as an induction agent in AAV. This multicenter, randomized, double-blind, placebo-controlled trial, involving 197 ANCA-positive patients, of whom 52% had renal disease and 28% had alveolar hemorrhage, compared rituximab with cyclophosphamide during induction. Both limbs received the same reducing glucocorticoid regimen. Rituximab was shown to be noninferior to cyclophosphamide in the rate of disease remission at 6 months in the absence of corticosteroid therapy. In this study, rituximab may have been superior to cyclophosphamide in inducing remission in patients with relapsing disease. The rate of adverse events was the same between the two treatment limbs.¹³⁸ Of course, both trials were limited by the follow-up time, and long-term outcome trials are required.

ANCA levels fall with rituximab treatment, but this fall often occurs more slowly than the improvement in renal disease activity.^{95,139} Induction of remission in patients is generally associated with complete peripheral B cell depletion following rituximab. B cell depletion, although to a lesser extent, also occurs with cyclophosphamide.¹³⁸ However, in studies of patients with relapsing disease, it has been shown that measurement of B cells peripherally is not a good surrogate marker for the risk of relapse because relapses may occur before the peripheral B cell population has recovered.¹³⁹

Methotrexate has been identified as another alternative agent to cyclophosphamide in the induction phase of limited disease in the absence of vital organ involvement and with serum creatinine less than 150 μ mol/L. The NORAM trial, involving 100 patients with newly diagnosed AAV, compared methotrexate with cyclophosphamide. Treatment was tapered and withdrawn in both limbs at 12 months. This study demonstrated noninferiority in the remission rate at 6 months between patients treated with

oral methotrexate versus those treated with oral cyclophosphamide. If treated with methotrexate, time to remission was longer in those with more extensive disease or lung involvement, suggesting that methotrexate is more appropriate in patients with limited early disease. The rate of leukopenia was significantly lower among those in the methotrexate limb. Relapse rates at 18 months were unacceptably high in both limbs, suggesting that immunosuppression should be continued for longer than 12 months.¹⁴⁰

A small study of 35 patients recently suggested that mycophenolate mofetil may be useful as an alternative agent to cyclophosphamide for induction therapy in those with generalized disease and moderate renal impairment.¹⁴¹ A larger, multicenter, randomized trial is being conducted by EUVAS to address this question (www.vasculitis.org).

Maintenance of Remission

It has been suggested that cyclophosphamide is used for the induction of remission, and another immunosuppressant agent, with fewer associated adverse events, is used to maintain remission. Four major agents have been used in this way: methotrexate, azathioprine, mycophenolate mofetil, and leflunomide. CYCAZAREM, a multicenter, randomized, controlled trial, compared azathioprine with cyclophosphamide to maintain remission, and compared relapse rates within 18 months of diagnosis. Investigators showed that following the induction of remission with cyclophosphamide for a minimum of 3 months, no difference in relapse rates was observed between the two limbs.¹⁴² Although in this trial no difference in adverse events between the two treatment limbs was reported, azathioprine is considered to be less toxic than cyclophosphamide. A retrospective study using historical controls also suggested that relapse rates were no different in those treated with azathioprine compared with cyclophosphamide during the maintenance phase of treatment. This study suggested that switching to azathioprine in patients with PR3-AAV, who remained ANCA-positive at the time of remission, was associated with a high risk of relapse.¹⁴³

Following induction of remission with cyclophosphamide, methotrexate is as effective as azathioprine in maintaining remission and may be used in those with normal renal function.¹⁴⁴

Small case series have suggested that mycophenolate mofetil is well tolerated when used as maintenance therapy.^{145,146} However, results from a large study of 154 adult patients randomized to receive azathioprine or mycophenolate for the maintenance of remission (IMPROVE study) suggested that azathioprine may be associated with fewer total relapses than mycophenolate.¹⁴⁷ However, no difference was observed in the number of major relapses or in damage sustained during the study as measured by the vasculitis damage index. No difference in adverse events was described in this study.

In a multicenter trial, following induction of remission with cyclophosphamide and prednisolone, 54 patients with GPA were randomized to receive leflunomide or methotrexate as maintenance therapy. This study was terminated prematurely owing to the high incidence of major relapse in those treated with methotrexate, but findings suggested that leflunomide was effective in preventing major relapses.

Conversely, leflunomide was associated with more adverse events than occurred with methotrexate. A dose of 30 mg/day of leflunomide was used; therefore, this may not be an appropriate dose.¹⁴⁸

Guidelines suggest that patients with AAV should continue on maintenance therapy for at least 24 months, maybe longer, following successful remission.¹⁴⁹ The IMPROVE study continued therapy for 40 months and reported relapse rates of almost 50%.¹⁴⁷

Adjuvant Therapy

Adjunct plasmapheresis in adult patients presenting with severe progressive renal failure (creatinine >500 µmol/L) has been shown, in the MEPEX study, to be superior to methylprednisolone in reducing the number of patients who remain dialysis dependent.¹⁵⁰ The underpinning principle of plasma exchange is the removal of circulating autoantibodies, with the by-product being the removal of other plasma proteins, including coagulation factors. No randomized trials have examined the use of plasma exchange in diffuse alveolar hemorrhage (DAH). A single retrospective review of 20 patients who presented with DAH associated with AAV treated with plasma exchange showed improved outcome with no complications of therapy compared with historical controls.¹⁵¹ A randomized trial conducted by EUVAS aims to investigate the efficacy of plasma exchange in addition to standard immunosuppressive therapy in AAV with pulmonary hemorrhage or renal involvement (GFR <50 mL/min) (www.vasculitis.org).

Alternative Agents

Alternative agents may be used for those who fail to respond to first-line treatment, or when there is cyclophosphamide intolerance. Rituximab has been shown to be effective in patients with refractory disease in whom maximal treatment with conventional therapy had not previously resulted in remission. Antilymphocyte therapies may also be effective in refractory disease. Treatment with antithymocyte globulin, which consists of polyclonal antibodies directed against T cell surface antigens and results in rapid T cell depletion, has been shown to be of benefit in a small pilot study of 15 patients.¹⁵² Deoxyspergualin is an antiproliferative agent with lymphocyte and macrophage inhibitory functions. In a study of patients with relapsing or refractory AAV treated for 6 months with deoxyspergualin, 42 of 44 patients achieved at least partial remission and 45% achieved full remission. However, relapse occurred in 44% with a median time of 170 days, and 53% developed severe or life-threatening treatment-related adverse events.¹⁵³ Campath, a humanized anti-CD52 antibody that depletes lymphocytes and monocytes, has shown benefit in refractory disease. However, it should be used with caution in those older than 50 years and dialysis dependent at the time of treatment.¹⁵⁴

Intravenous immunoglobulin (IVIG) has been used to induce remission in AAV. In a double-blind controlled trial, 34 patients were randomized to receive a single course of IVIG or a placebo, alongside conventional treatment. Those who received IVIG had significantly reduced Birmingham Vasculitis Activity Score (BVAS) at 3 months

Table 89-4 EULAR Recommendations on the Management of AAV (12 of 15 Applicable to AAV)

1. Manage in collaboration with, or at, centers of expertise
2. ANCA testing should be performed only in an appropriate clinical context
3. A positive biopsy is strongly supportive of vasculitis—recommend the procedure to assist diagnosis and further evaluation for patients suspected of having vasculitis
4. Structured clinical assessment, urinalysis, and other basic laboratory tests at each clinical visit
5. Categorize according to different levels of severity to assist treatment decisions
6. Cyclophosphamide (oral or IV) and glucocorticoids for remission induction
7. Combination of methotrexate and glucocorticoid as a less toxic alternative to cyclophosphamide for the induction of remission in non-organ-threatening or non-life-threatening ANCA-associated vasculitis
8. Use of high-dose glucocorticoids as an important part of remission induction therapy; high dose continued for the first month (usual practice to start at 1 mg/kg/day). Dosage should not be reduced to <15 mg/day in first month
9. Plasma exchange for selected patients with rapidly progressive severe renal disease to improve renal survival
10. Remission maintenance therapy with a combination of low-dose glucocorticoid therapy and azathioprine/leflunomide/methotrexate
11. Alternative immunomodulatory therapy choices should be considered for patients who do not achieve remission or relapse on maximal doses of standard therapy
12. Investigation of persistent unexplained hematuria in patients with prior exposure to cyclophosphamide

AAV, antineutrophil cytoplasm antibody–associated vasculitides; ANCA, antineutrophil cytoplasm antibody; EULAR, European League Against Rheumatism.

From Mukhtyar C, Guillevin L, Cid MC, et al: EULAR recommendations for the management of primary small and medium vessel vasculitis, *Ann Rheum Dis* 68:310–317, 2009.

compared with the placebo limb, but this effect was not maintained beyond 3 months.¹⁵⁵ Six months of IVIG treatment has been shown to be effective in inducing remission in the context of disease relapse,¹⁵⁶ with a study of six patients also suggesting effectiveness of IVIG as sole therapy.¹⁵⁷ IVIG may be useful where significant immunosuppression should be avoided.

EULAR has recently produced guidelines to help guide the management of patients with AAV¹³¹ (Table 89-4). However, it must be noted that most studies have excluded patients with AGPA.

Treatment of Allergic Granulomatosis with Polyangiitis

Patients without poor prognostic disease according to the FFS can be managed by corticosteroids alone.¹⁵⁸ However, relapse is common, with 35% of patients relapsing with a mean follow-up of 56 months. Long-term steroids were necessary in 79% mainly owing to asthma. In patients with one or more poor prognostic factors, induction therapy with corticosteroids and cyclophosphamide is necessary.¹²¹ No maintenance therapy was prescribed in this study, and relapses were common, occurring in 74%. As with those patients without poor prognostic factors, long-term use of steroids occurred in the majority (81%), even after a median follow-up of 8 years.

Patient survival with these regimens is good; those without adverse prognostic signs have 5-year survival of 97%,¹⁵⁸ and those with more severe disease have 92% survival at 8 years.¹²¹ However, the optimal duration of maintenance therapy is unknown, and many require long-term therapy for asthma symptoms.

Up to 10% of patients are refractory to conventional therapy. New therapies are under investigation. Rituximab has been effective in a few cases^{159,160}; however it has been reported to provoke severe bronchospasm.¹⁶¹ Small open-label studies are in progress to assess the efficacy and safety of rituximab and mepolizumab, an anti-IL-5 monoclonal antibody, in AGPA.

Adverse Events

Despite improvement in survival resulting from improved treatment strategies, a recent EUVAS short-term outcome study, which included 524 patients prospectively recruited into four clinical trials, reported a 1-year mortality probability of 11.1%.¹⁶² The cause of death was related to an adverse event of treatment in 59%, and infection was the overwhelming factor. Active vasculitis accounted for only 14% of deaths. This study highlights the burden of using nonselective immunosuppressant agents, which suppress the whole immune system, not just the production of ANCA. Patients receiving such treatments, including glucocorticoids, are at increased risk for opportunistic infection, with respiratory tract infection and generalized septicemia being the most common infections in the EUVAS study previously discussed. Factors predictive of infection include age, severity of renal dysfunction, leukopenia, and intensity and duration of immunosuppression. Guidelines advocate the use of prophylaxis against *Pneumocystis jiroveci* in patients receiving cyclophosphamide.¹³¹ Influenza vaccinations have been shown to be safe and effective in AAV without association with relapse in a retrospective study of 230 patients.¹⁶³ Rituximab is associated with an impaired secondary humoral response, making immunization ineffective during treatment.¹⁶⁴

Other adverse events are specific to treatments. Glucocorticoids are known to have a broad adverse event profile, including steroid-associated diabetes, avascular necrosis, and ocular cataract formation; monitoring for all of these should be provided during treatment. Prophylaxis against osteoporosis¹³¹ and peptic ulceration has become routine, especially in those receiving high-dose corticosteroids. The adverse events associated with cyclophosphamide have already been highlighted. Concomitant treatment with mesna, which binds to the toxic metabolite of cyclophosphamide, is advised on the first day of a cyclophosphamide pulse and in oral regimens¹³¹ to reduce the risk of bladder toxicity.⁸⁶ Male and female infertility is a recognized complication of cyclophosphamide therapy in autoimmune disease.^{149,165} In females, infertility is related to high cumulative doses and older age at treatment.¹⁶⁵ Minimizing the dose of cyclophosphamide is important, as is the continuing development of methods of fertility preservation.^{166,167} Patients should be counseled as to the risk of infertility, and cryopreservation of sperm and oocytes should be offered if appropriate.¹⁴⁹

Adverse events can also be attributable to the disease itself. In a study of 198 patients, followed for a median of 6.1 years, it was shown that AAV is associated with increased risk of venous thromboembolism, especially when the disease is active.¹⁶⁸ Avoidance of classic risk factors for venous thromboembolism is therefore important, as is the use of prophylaxis during prolonged immobility. Because patients are now surviving their acute illness, the long-term consequences of disease activity need to be considered, along with the already discussed burden of therapy.

OUTCOME

Over the past 30 years, treatment has improved outcomes for patients with AAV. Most patients respond to treatment, and 85% achieve remission. Older age may predict treatment resistance.¹⁶⁹ Patient survival is reported as 45% to 91% at 5 years and as 75% to 88% at 10 years compared with 80% mortality at 2 years if left untreated.¹³³

Despite advances in therapy, patients continue to have substantially higher mortality than a matched background population, as was shown by a recent study of long-term outcomes of patients recruited to EUVAS studies.¹³⁰ The mortality rate ratio was 2.6 compared with the normal population, with advanced renal failure, increasing age, and a high BVAS being the main predictors of an adverse outcome. Several other studies have identified increasing age and worsening renal function as poor prognostic markers.^{170,171} In this study, no difference in survival was reported between patients with GPA and those with MPA in contrast to other studies.^{170,172} Mortality is highest in the first year, with 1-, 2-, and 5-year survival of 88%, 85%, and 78%. Disease and therapy-related deaths, particularly infection, account for most deaths in the first year. Infection remains an important cause of death even beyond 1 year, but malignancy and cardiovascular disease are also common.¹³⁰

End-stage kidney disease (ESKD) is not uncommon in patients with AAV; approximately 20% of those presenting who have evidence of renal involvement will develop ESKD by 5 years. In a multivariate analysis, renal survival was best predicted by presenting serum creatinine and percentage of normal glomeruli in the diagnostic biopsy.¹²² Patients who develop ESKD should be considered for transplantation. Using United Network for Organ Sharing (UNOS) data from 1996-2007, 919 patients with ESKD secondary to GPA were identified. Adjusted outcomes for graft loss, death, and functional graft loss were better in those patients with GPA compared with other causes of ESKD.¹⁷³ Outcome in those patients who remain on dialysis is similar to that with other causes of ESKD.⁸⁷

Cardiovascular disease is more common in patients with AAV than in the healthy population or in patients with matched levels of chronic kidney disease.^{110,111} It is currently unclear whether this is related to persistent inflammation or to therapy with prolonged steroid use. Malignancy rates in treated AAV patients are also higher than in the healthy population, particularly nonmelanoma skin and bladder cancer and acute myeloid leukemia.^{86,174-176} The cumulative dose of cyclophosphamide is important in determining risk of cancer; patients receiving more than 36 g are at greatest risk.¹⁷⁴ Preliminary results from the EUVAS group suggest

that the philosophy of minimizing cyclophosphamide usage may be proving correct; a follow-up study of patients recruited to clinical trials revealed only nonmelanoma skin cancer to be substantially increased compared with the healthy population.^{176a}

The clinical course in patients with AAV is difficult to predict; approximately 50% of patients will relapse over 5 years. Predictors of relapse have included anti-PR3 antibodies, lung and upper respiratory involvement,¹⁷⁷ age,¹⁷⁸ nasal carriage of *S. aureus*,³⁵ and absence of severe renal involvement.^{178,179} Patients with ESKD have lower rates of relapse.^{87,162} Daily oral cyclophosphamide may be more effective than intermittent cyclophosphamide but at the expense of higher risk of death and adverse events.¹⁷⁹⁻¹⁸¹

Using microarray analysis of purified T cells, a CD8⁺ T cell transcription signature has been identified that can identify patients at risk of relapse. The subset of genes defining the poor prognostic group was enriched for genes involved in the interleukin (IL)-7 receptor pathway and T cell receptor signaling, and for genes expressed by memory T cells. A model using only three genes—*ITAG2*, *PTPN22*, and *NOTCH1*—was predictive of the poor prognostic group. However, this signature was not discernible following treatment.¹⁸² Confirmation of this signature by others raises the possibility of individualized therapy.

SUMMARY

Understanding of the causes and pathogenic mechanisms underlying AAV has progressed apace over the past 20 years. The central place of ANCA and immune processes is appreciated. The mortality incurred by patients suffering from AAV has fallen steadily, but the chronic relapsing nature of the disease, without definitive treatments that offer cure, continues to extract a heavy toll on the health of afflicted individuals of all ages. Understanding of the most efficacious ways with which to control disease using corticosteroids, cyclophosphamide, other immune suppressants, and plasma exchange has increased through use of randomized prospective clinical trials. However, although rituximab holds promise, no therapy has yet been licensed for AAV. Despite the rarity of the condition, the large unmet need for safe, effective therapies remains a challenge to pharmaceutical companies, particularly because mechanisms underpinning the disease are understood sufficiently to provide realistic targets for new therapies.

Polyarteritis Nodosa and Related Disorders

RAASHID LUQMANI

KEY POINTS

Polyarteritis nodosa (PAN), characterized by vasculitis of medium-sized arteries with few or no immune deposits, is relatively rare, especially in comparison with patients with microscopic polyangiitis or granulomatosis with polyangiitis.

One form of PAN is caused by hepatitis B virus and usually responds well to antiviral therapy, plasma exchange, and/or glucocorticoids.

Non-hepatitis B-associated PAN should be treated aggressively with cyclophosphamide and glucocorticoids, using the same approach as for systemic small vessel vasculitis.

The true incidence and prevalence of nonhepatitis PAN is around 1 per million per annum.

A significant reduction in the incidence of PAN has occurred due to a decreasing incidence of hepatitis B infection.

Presenting features of PAN include insidious onset of weight loss, purpuric skin lesions together with mononeuritis multiplex, and symptoms of mesenteric ischemia.

Glomerular renal disease is absent in PAN and should prompt consideration of other diagnoses.

Hematuria with renal impairment is rare but can occur in the presence of renal infarction.

There is much confusion regarding the term “cutaneous PAN,” which in some cases may represent a subset of patients with early PAN; in others it is a distinct condition.

Buerger’s disease, thromboangiitis obliterans, affects both sexes and involves the upper and lower extremities.

The role of tobacco use in Buerger’s disease is clearly established but not understood.

Rare forms of vasculitis are described, but the evidence base for treatment is limited.

POLYARTERITIS NODOSA

Definition and Classification

The term *periarteritis nodosa* was originally introduced in 1866 and subsequently used to describe any form of systemic vasculitis.¹ The term has been modified to polyarteritis nodosa (PAN), and the definition has been improved to consist of “necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules.”²

The American College of Rheumatology (ACR) criteria, which can be used to classify patients as having PAN, in

order to distinguish them from patients with other forms of primary systemic vasculitis, do not differentiate between PAN and microscopic polyangiitis (MPA); both conditions are included under the umbrella of PAN. Three of 10 criteria (listed in [Table 90-1](#)) are required.³

The sensitivity of the ACR criteria for PAN (or MPA) is 82.2%, with a specificity of 86.6% when used to classify the disease.³ Definitions of vasculitis (including PAN) were published in 1994 by the Chapel Hill Consensus Conference (CHCC).² Microscopic polyangiitis, granulomatosis with polyangiitis (GPA) (formerly Wegener’s granulomatosis), and Churg-Strauss syndrome were distinguished from PAN on the basis of the pathologic findings of small vessel involvement in the former three diseases; by contrast, small vessel involvement is absent in PAN.

There has been, and still is, much confusion in the terms used to describe patients with different forms of vasculitis. It is worth considering this for a moment because, on reviewing patients who have previously been given the label of “PAN,” the clinical features at presentation might actually suggest another form of vasculitis, typically MPA or GPA. In an attempt to rationalize the naming of different forms of vasculitis, the European Medicines Agency (EMA) produced an algorithm to assist in the classification of patients with systemic small and medium vessel primary systemic vasculitis.⁴ A decision tree approach was used, effectively putting PAN at the bottom of the tree.⁴ In other words, patients were assigned to any other form of vasculitis, and only as a last resort, if no other diagnosis was made, the term PAN was applied. Perhaps this might seem a rather negative view of the condition, but because of the overuse of the term PAN in preference to others in the past, the true incidence and prevalence of PAN are actually low.

The EMA algorithm is particularly useful because MPA is a more common condition than PAN but is absent from the ACR classification criteria (it is considered part of PAN), whereas in the CHCC definition PAN and MPA are treated as separate entities. There are important differences between PAN and MPA in terms of pathogenesis, organ involvement, tendency to relapse, and prognosis.⁵ In the CHCC definition PAN is a medium vessel disease; by comparison, MPA is predominantly a small vessel disease that includes glomerulonephritis and pulmonary capillaritis.²

Patients are assessed using the EMA algorithm if they have a clinical diagnosis of an antineutrophil cytoplasm antibody (ANCA)-associated vasculitis or PAN. In the algorithm, PAN is regarded as a diagnosis of exclusion. The first part of the algorithm is to determine whether the patient fulfills the Lanham⁶ or ACR criteria⁷ for Churg-Strauss syndrome (CSS). If they do, they are classified as having CSS. If not, the next step is to determine whether

Table 90-1 American College of Rheumatology Criteria for Classification of Polyarteritis Nodosa (and Microscopic Polyangiitis)

Weight loss ≥ 4 kg
Livedo reticularis
Testicular pain or tenderness
Myalgias, weakness, or leg tenderness
Mononeuropathy or polyneuropathy
Diastolic blood pressure >90 mm Hg
Elevated blood urea nitrogen or creatinine
Hepatitis B virus
Arteriographic abnormality
Biopsy of small or medium-sized artery containing polymorphonuclear neutrophils

From Lightfoot RW, Michel BA, Bloch DA, et al: The American College of Rheumatology 1990 criteria for the classification of polyarteritis nodosa, *Arthritis Rheum* 33:1088–1093, 1990.

they fulfill the ACR criteria or CHCC definition for GPA^{2,8} either by direct evidence with histology or with appropriate surrogate markers and a positive ANCA. If they fulfill these requirements, they are classified as having GPA. If not, they proceed down the algorithm to see whether they fulfill a definition of MPA.² This is either by histology showing small vessel vasculitis or glomerulonephritis and no surrogate markers for GPA or with surrogate markers of glomerulonephritis and a positive ANCA. Only when CSS, GPA, and MPA are excluded is a diagnosis of PAN possible in this schema. To fulfill the definition of PAN in this algorithm, there must be histology or angiographic features consistent with the diagnosis. Any remaining patients are determined to be unclassifiable. The initial validation of the algorithm made use of paper cases assessed by a number of experts in vasculitis. In fact, every case was assigned to one of the conditions, without the need to describe any case as unclassifiable. This may not reflect clinical practice, where some patients appear to have an overlap between different forms of vasculitis or incomplete forms of a vasculitis. This is an important issue and has started to be addressed by a recent task force on classification and diagnostic tests in vasculitis.⁹

The French Vasculitis Study Group proposed a set of predictive items (Table 90-2) to be used as diagnostic criteria.¹⁰ The items were derived from 949 patients with known

vasculitis (including 262 described as having PAN) and not from undifferentiated patients, and therefore they are actually another form of classification criteria.

The combination of nonspecific constitutional symptoms and ischemic symptoms in one or more organ systems should alert the physician to the possibility of a systemic vasculitis. PAN typically presents with nonspecific symptoms such as fever, weight loss, and myalgia in combination with single or multiorgan manifestations resulting from ischemia or infarction. The commonest organ manifestation is neurologic with mononeuritis multiplex, followed by skin lesions, abdominal pain from mesenteric ischemia, and renal infarction. Testicular pain due to ischemic orchitis is a classic feature of PAN but is rare at presentation. Some patients may present with an acute surgical abdomen due to bowel, liver, spleen, or pancreatic infarction. Myocardial infarction, ischemic cardiomyopathy, optic ischemia, and ischemic complications of the female genital tract are possible but unusual.

Epidemiology

The epidemiology of PAN has changed over time. Effective hepatitis B virus (HBV) immunization programs, improved blood screening for HBV, and major changes in definition and classification of vasculitis have resulted in a substantial reduction in incidence of PAN. Before the CHCC definition in 1994, MPA was included in the incidence and prevalence estimates. The impact of this is highlighted in a study comparing the incidence of PAN in three European regions: 4.4 to 9.7 per million by the ACR criteria versus 0 to 0.9 per million with the CHCC definition.¹¹

The incidence of PAN is 2 to 9 per million in Europe and the United States by ACR criteria.¹² A higher incidence of 16 per million (by CHCC definition) is reported in Kuwait¹³ and 77 per million described in an Alaskan population endemic for HBV, although it was based on only 13 actual cases of HBV PAN (in a study performed before ACR criteria or CHCC definitions).¹⁴ The prevalence of PAN by ACR criteria is 31 to 33 per million in Western Europe¹⁵⁻¹⁷; 2 to 9 per million in Germany by CHCC definition.¹⁸ A small study from Australia assessed the incidence and prevalence of different sorts of vasculitis between 1995 and 2005 in one area, suggesting a fall in the incidence of PAN from 2.3 per million per annum to 1.1 per million per annum.¹⁹ A study from 2009 assessed the incidence and survival of patients with different forms of vasculitis and estimated the incidence of PAN to be 0.9 (between 0 and 1.7) per million per annum. This compares with an almost 10-fold difference in incidence of GPA and MPA (between 9.8 and 10.1 per million per annum).²⁰

PAN can occur at any age, but the commonest age range at diagnosis is 40 to 60 years. There is no clear gender difference.¹⁷ In a multiethnic population from France, patients with European ancestry had a higher prevalence of PAN compared with those without.¹⁶

Etiology and Pathogenesis

PAN is often related to infection with hepatitis B.²¹ The incidence of HBV-related PAN follows HBV infection rates, previously accounting for 7% to 38.5% of patients

Table 90-2 Predictive Variables for Classification of Polyarteritis Nodosa (PAN)

Variable	Positive Prediction for PAN	Negative Prediction for PAN
Positive hepatitis B serology	+	
Arteriographic abnormalities	+	
Mononeuropathy or polyneuropathy	+	
Positive antineutrophil cytoplasm antibody		+
Asthma		+
Ear, nose, or throat signs		+
Glomerulopathy		+
Cryoglobulinemia		+

Modified from Henegar C, Pagnoux C, Puéchal X, et al: A paradigm of diagnostic criteria for polyarteritis nodosa: analysis of a series of 949 patients with vasculitides, *Arthritis Rheum* 58(5):1528–1538, 2008.

diagnosed with PAN.^{16,22} The prevalence of HBV-related PAN has reduced in recent years as a result of vaccination for HBV and improved screening of blood products.^{16,23} PAN develops in 1% to 5% of patients with HBV infection,¹⁴ which confers an approximately 1000-fold increase in risk compared with the background population.¹² By contrast, in Alaska, an area endemic for HBV, there is a substantial increased annual incidence of HBV PAN (77 per million), primarily due to vertical transmission.¹⁴ Documented exposure to HBV occurs from blood products, intravenous drug use, and sexual contact. Screening of blood products for HBV and mass vaccination against the virus has successfully reduced the incidence of HBV PAN, as shown in French patients with the proportion of PAN due to HBV falling from 38.5% in the 1970s to 17.4% by the period 1997-2002.²⁴

In HBV-related PAN the postulated mechanism of vasculitis includes direct vessel injury by replicating virus or deposition of immune complexes. Deposition of immune complexes leads to activation of the complement cascade, resulting in an inflammatory response and subsequent endothelial damage. The vasculitis typically occurs within the first few months following HBV infection and may be the first presenting feature of this infection. Evidence for the pathogenic nature of HBV and immune complexes is supported by the effectiveness of a treatment strategy to eradicate HBV with antiviral therapy and removal of immune complexes by plasmapheresis without the need for long-term immunosuppression.^{24,25}

Saadoun and colleagues²⁶ described 31 patients who had hepatitis C virus (HCV)-associated vasculitis, which they classified as PAN according to ACR criteria and CHCC definitions. This cohort, representing approximately one-fifth of their HCV vasculitis patients, had more frequent fever, weight loss, severe hypertension, gastrointestinal tract involvement, severe acute sensory-motor multifocal mononeuropathy, kidney and liver microaneurysms, and increased C-reactive protein compared with other HCV vasculitis patients. By contrast, their response to therapy was more successful.

In the remainder of patients with PAN, the etiology is unknown. Genetic, infectious, and environmental agents are thought to be important, but there is no conclusive evidence.¹¹ The fact that idiopathic PAN responds to immunosuppressive therapy suggests an immunologic mechanism. In idiopathic PAN the role of immune complexes is unclear. There is evidence of endothelial dysfunction, an increase in inflammatory cytokines, and an increase in expression of adhesion molecules. There is a propensity for the inflammatory lesions to occur at the sites of bifurcation in vessels, where there is most likely to be turbulent flow. Following the inciting event, there is focal and segmental necrotizing inflammation of medium- and small-sized arteries. This leads to intimal proliferation with subsequent thrombosis, resulting in ischemia or infarction of the organ or tissue supplied by these arteries.

There are case reports describing the development of PAN in patients with pre-existing hairy cell leukemia.^{27,28} Most cases had undergone splenectomy before the development of PAN. Potential mechanisms for the association between hairy cell leukemia and PAN include

cross-reactivity of antibodies between the tumor cells and the endothelium, direct damage of the endothelium by tumor cells, and local production of proinflammatory cytokines triggering vessel wall damage.²⁸

Pathologic Features

Due to the protean manifestations of the disease, a number of different sites can be biopsied. Sampling should be directed by the pattern of clinical involvement suggested by the history or physical examination. Muscle, peripheral nerves, kidney, testis and rectum, when involved, provide the best yield. Skin involvement and a positive skin biopsy do not always indicate evidence of systemic involvement²⁹⁻³¹ (see section on cutaneous PAN).

A biopsy of a medium-sized artery will show “focal and segmental” transmural necrotizing inflammation^{30,31} (Figure 90-1). If there are any clinical or laboratory features indicating involvement of small vessels, further assessment should be undertaken because it suggests an alternative form of vasculitis such as MPA.³²

Inflammatory change at the bifurcation of vessels is reported to be common. The coexistence of different stages of inflammation and scarring, as well as normal vessel wall, is typical in PAN. Areas of acute inflammation will usually have a pleomorphic cellular infiltrate of lymphocytes, neutrophils, macrophages, and eosinophils. Aneurysms can occur at the site of active lesions, and this morphologic appearance is what led to the term “nodosa” (Figure 90-2). Proliferative scarring in other areas may lead to vessel narrowing.³⁰⁻³³

Clinical Features

PAN can present at any age, but it typically occurs in the age range of 40 to 60. There is no significant gender difference. The diagnosis can be difficult to make because individual features can occur in a variety of other diseases. Table

Figure 90-1 This cross-section of a medium-sized artery demonstrates transmural inflammation with infiltrating lymphocytes typical of polyarteritis nodosa. The lesion is at an early stage, before occlusion of the whole vessel or weakness of the vessel wall leading to aneurysm formation.

Figure 90-2 This celiac axis angiogram from a patient with polyarteritis nodosa demonstrates an irregular vascular pattern with small aneurysms in the hepatic vessels.

90-3 summarizes the clinical findings in PAN. The presence of nonspecific constitutional symptoms such as fever, weight loss, joint and muscle pains (found in 65% to 80% of cases of PAN), and ischemic symptoms in one or more organ system should raise the possibility of a systemic vasculitis.^{17,24} Organ-specific manifestations may be present at the onset of disease, or there may be a more low-grade course, resulting in the development of specific organ involvement months to years later. Involvement of organs may be in isolation or as multisystem disease. In a Swedish series, the most common manifestations occurred at disease onset: nervous system (55%), skin (44%), abdominal (33%), and renal (11%).¹⁷ A review of 348 patients diagnosed as having PAN since the 1960s³⁴ suggested that their mean age of diagnosis was 51 and the most frequent symptoms were generalized features in more than 90% of cases, neurologic features in 79%, skin involvement in 50%, abdominal involvement in 36%, hypertension in 35%, renal artery microaneurysms in 66%, and histologically proven PAN in 70%. The subset of 123 patients with hepatitis B–associated PAN was more likely to suffer peripheral neuropathy, abdominal pain, cardiomyopathy, orchitis, and hypertension compared with 225 non-HBV PAN patients. The relapse rate was 22% over a follow-up of 6 years (28% for non-HBV-related PAN compared with 11% for HBV PAN). The mortality rate was 25% overall (20% for

Table 90-3 Organ Involvement in Polyarteritis Nodosa (PAN)

System	Comment	Frequency	Reference
Constitutional	Fever and weight loss (current and previous)	>90%	34
Musculoskeletal	Arthritis, arthralgia, myalgia, or weakness; when muscle is involved, it provides a useful site for biopsy	24%-80%	17,24
Skin	Purpura, nodules, livedo reticularis, ulcers, bullous or vesicular eruptions, and segmental skin edema	44%-50%	17,34-36
Cardiovascular	Cardiac ischemia, cardiomyopathy, hypertension	35%	24,30,34
Ear, nose, and throat	No involvement. Nasal crusting, sinusitis, and hearing loss suggest an alternative diagnosis such as granulomatosis with polyangiitis	None	
Respiratory	Lung involvement not seen in PAN; abnormal respiratory findings suggest alternative diagnosis	None	
Abdominal	Pain is an early feature of mesenteric artery involvement. Progressive involvement may cause bowel, liver, or splenic infarction; bowel perforation; or bleeding from a ruptured arterial aneurysm. Less common presentations include appendicitis, pancreatitis, or cholecystitis as a result of ischemia or infarction The presence of abdominal tenderness or peritonitis and blood loss on rectal examination should be assessed	33%-36%	17,34
Renal	Vasculitis involving the renal arteries is present in many cases but does not commonly give rise to clinical features. It can present with renal impairment, renal infarcts, or rupture of renal arterial aneurysms. Glomerular ischemia may result in mild proteinuria or hematuria, but red cell casts are absent because glomerular inflammation is not a feature. If there is evidence of glomerular inflammation, then an alternative diagnosis such as microscopic polyangiitis or granulomatosis with polyangiitis must be considered. Hypertension is a manifestation of renal ischemia causing activation of the renin-angiotensin system	11%-66%	17,34
Nervous system	Mononeuritis multiplex, with sensory symptoms preceding motor deficits. Central nervous system involvement is a less frequent finding and can present with encephalopathy, seizures, and stroke	55%-79%	17,34
Ocular	Visual impairment, retinal hemorrhage, and optic ischemia	Rare	24,30
Other	Breast or uterine involvement is rare; testicular pain from ischemic orchitis is a characteristic feature, albeit an uncommon presentation	Rare	37,38

non-HBV PAN compared with 34% in HBV-PAN). Five-year relapse-free survival was higher in patients with HBV-related PAN (67% compared with 59%). The conclusion was that non-HBV PAN in particular had a high mortality, especially involving the elderly, and was worse in those patients with skin manifestations.

Clinical Assessment of Patients

In patients where vasculitis is suspected, a thorough history and physical examination is necessary to identify the potential organ systems involved. Use of the Birmingham Vasculitis Activity Score as a checklist of important features of the disease is recommended³⁹ to guide further targeted investigation and to be used subsequently in devising a management plan for treatment. Table 90-3 lists the typical features to be assessed in suspected PAN.

Laboratory Testing

No specific laboratory tests are available to diagnose PAN, but some may be useful to support the diagnosis, identify organs that may be affected, and rule out alternative diagnoses (Table 90-4).

Radiology

The angiogram is the imaging modality of choice, but increasingly it is being replaced by less invasive, safer techniques. The classic findings are multiple small aneurysms, vessel ectasia, and focal occlusive lesions in medium-sized

vessels, typically in the renal and mesenteric arteries. The reported sensitivity of angiography is as high as 89% and specificity 90% when performed in individuals suspected of having vasculitis.⁴⁰ Magnetic resonance (MR) or computed tomography (CT) angiography are less invasive alternatives to conventional angiography but are much less sensitive in demonstrating microaneurysms.⁴¹ They do have the advantage of being able to demonstrate areas of renal infarction and other potential pathology. In the setting of high suspicion of PAN and normal CT or MR angiography, it is still necessary to proceed to conventional angiography. Doppler ultrasound can identify renal and hepatic aneurysms related to PAN.⁴² A plain chest radiograph may be useful for excluding other diseases such as other vasculitides that may affect the lungs and also to exclude infection.

Polyarteritis Nodosa in Children

Pediatric cases of polyarteritis are also well described. In a review of 110 patients, with a mean age of 9 (male-to-female ratio equal), one-third were classified as having cutaneous PAN. Only 5% had classic PAN associated with hepatitis B surface antigen, whereas 80% were described as having MPA associated with ANCA and 57% had systemic PAN.⁴³

Microscopic Polyangiitis versus Polyarteritis Nodosa

A comparison of patients with PAN and MPA showed a difference in the skin manifestations of the 162 patients

Table 90-4 Investigations for Patients with Suspected Polyarteritis Nodosa (PAN)

Test	Supports Diagnosis of PAN	Supports an Alternative Diagnosis	Comment
Elevated C-reactive protein	+		Supports the presence of systemic inflammation
Elevated sedimentation rate	+		Supports the presence of systemic inflammation
Elevated serum creatinine	+/-	+/-	Raised serum creatinine, typically without hematuria or proteinuria on urinalysis, may indicate renal ischemia or infarction. Significant proteinuria or hematuria (especially red cell casts) would suggest glomerular disease, which is <i>not</i> a feature of PAN
Abnormal liver function tests	+		May suggest hepatitis, either from HBV or as a result of ischemic hepatitis from PAN affecting the hepatic arteries
Positive HBV serology	+		Seen in HBV PAN
Anemia	+		Due to chronic inflammation or from gastrointestinal blood loss
Positive ANCA		+	A positive ANCA would suggest an alternative type of vasculitis such as granulomatosis with polyangiitis or MPA
Elevated creatine kinase	+/-	+/-	Normal or mildly elevated, despite any muscle involvement
Blood cultures		+	To exclude endocarditis or other infective mimic of vasculitis
Positive HCV serology and cryoglobulins		+	HCV associated with a skin limited manifestation of PAN, but typically it is associated with a small vessel vasculitis related to cryoglobulinemia
Positive rheumatoid factor and ACPA		+	To rule out rheumatoid arthritis, especially in the context of a patient presenting predominantly with arthritis
Positive ANA and anti-dsDNA		+	In patients with clinical features consistent with SLE or other connective tissue disease
HIV positive		+	

ACPA, anticitrullinated protein antibody; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasm antibody; dsDNA, double-stranded deoxyribonucleic acid; ESR, erythrocyte sedimentation rate; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; MPA, microscopic polyangiitis; SLE, systemic lupus erythematosus.

with MPA and 248 with PAN.⁴⁴ There was a greater frequency of purpura (26%) in MPA compared with only 19% in PAN. By contrast, urticaria was more common in PAN (6% vs. 1.2%). The presence or absence of HBV infection—influenced skin manifestations were less common (only 30%) in HBV-positive patients compared with HBV-negative patients (54%). Histologic examination of the skin, however, was identical in patients with either MPA or PAN. (See Chapter 89 for more details on MPA.)

Cutaneous Polyarteritis Nodosa

The term *cutaneous PAN* usually implies a separate entity from PAN that is limited to the skin, but there is some uncertainty as to whether these are actually just early cases of PAN and whether progression to PAN will occur. Cutaneous PAN is defined as a skin-limited form of PAN that is usually considered a separate clinical entity to systemic PAN. Pathologically the findings on skin biopsy are indistinguishable between the two.³¹ In a retrospective review of cutaneous PAN patients from a Japanese group, 22 patients with histologically proven cutaneous vasculitis were followed: 32% had a peripheral neuropathy, and 27% had myalgia, suggesting a need to revise the current criteria to differentiate between the two entities of cutaneous PAN and PAN. It was suggested that the two conditions were indeed separate, but cutaneous PAN is not confined to the skin.⁴⁵ HCV infection has been associated with cutaneous PAN in one retrospective study of 16 patients, in which 5 individuals were found to have HCV infection.⁴⁶

Hepatitis B Virus Polyarteritis Nodosa

Hepatitis B vasculitis occurs in individuals with chronic hepatitis B antigenemia, most of whom have active liver disease.²¹ The manifestations vary considerably, from diffuse small vessel vasculitis predominantly in the skin to larger vessel lesions typical of PAN. Clinical symptoms may include the entire spectrum of vasculitic manifestations, from purpura and other rashes to abdominal pain, hypertension, renal disease, and stroke. HBV-associated PAN is an increasingly rare condition as a result of better immunization programs against hepatitis B. A cohort of 115 patients with PAN was reviewed on the basis of inclusion into studies between 1972 and 2002.²⁴ Treatment of hepatitis B–related PAN with steroids plus an antiviral agent plus plasmapheresis resulted in 81% of patients achieving remission and a subsequent 10% relapse rate. However, 36% did subsequently die. Seroconversion of hepatitis B antibody status was associated with complete remission and

no relapse. In patients who were ANCA negative, the major cause of death was gut involvement. Plasmapheresis achieved not only a control of disease in combination with steroids and antiviral therapy but facilitated seroconversion to prevent secondary long-term complications from HBV infections such as liver involvement.

Non-Hepatitis B Virus Polyarteritis Nodosa

The French Vasculitis Study Group has combined data on PAN and microscopic polyangiitis focusing more on the severity of disease manifestations rather than the type of disease in their studies of treatment or outcome. For example, Ribi and colleagues⁵⁰ described the outcome of 124 patients with a new diagnosis of either PAN or MPA in whom the outcome was likely to be good (based on a lack of poor prognostic factors as measured by the Five Factor Score). All patients were treated with corticosteroids only followed by either azathioprine or cyclophosphamide if they relapsed. Ninety-eight of these patients achieved remission with steroids alone, but 46 of these patients relapsed. Primary treatment with steroids failed to control the disease in 26 patients, and 49 of the original 124 patients required additional immunosuppression. Similar rates of improvement were documented by using either azathioprine or cyclophosphamide. Therefore despite the absence of poor prognostic factors, only around 50% of patients could be managed with corticosteroids alone. A study of plasma exchange in 62 patients with a mixture of Churg-Strauss syndrome and what was described as PAN suggested that there was no clinical benefit from adding plasma exchange to standard treatment with pulse intermittent high-dose cyclophosphamide and steroid. This study from the mid-1990s describes patients with “PAN,” but most of these patients probably had MPA.⁵¹ Table 90-5 lists treatment regimens for non-HBV PAN that are based on the European League Against Rheumatism guidelines on management of small and medium vessel vasculitis.⁵²

Treatment of Polyarteritis Nodosa

Uncontrolled vasculitis accounts for 58% to 73% of deaths occurring within the first year of diagnosis.⁴⁷⁻⁴⁹ Management of non-HBV PAN should be appropriate to the severity of the disease as defined by the five-factor prognostic score and includes aggressive immunosuppression with corticosteroids and cyclophosphamide in patients with Five Factor Score values of at least one.⁴⁹ Patients with HBV-related PAN should be treated with high-dose corticosteroids followed by combination plasma exchange and antiviral agents to

Table 90-5 Pulsed Cyclophosphamide and Methylprednisolone for Non-Hepatitis B Virus Polyarteritis Nodosa

Phase	Drug	Dose	Route	Frequency	Duration
Induction	Cyclophosphamide	15 mg/kg per pulse	IV	Every 2 wk × 3, then every 3 wk × 3-6	3-6 mo
Induction	Methylprednisolone	10 mg/kg	IV	Every 2 wk × 3, then every 3 wk × 3-6	
Maintenance	Azathioprine	2 mg/kg/day	Oral	Daily	18-24 mo
Maintenance	Prednisone	7.5 mg/day	Oral	Daily	18-24 mo

Modified from Mukhtyar C, Guillevin L, Cid MC, et al: EULAR recommendations for management of primary small and medium vessel vasculitis, *Ann Rheum Dis* 68:310–317, 2009.

reduce early mortality from vasculitis and late mortality from the consequences of chronic hepatitis.²⁴

Outcome

Earlier diagnosis and initiation of treatment has improved outcomes. In non-HBV PAN the 7-year survival rate is 79%, compared with a 5-year survival rate of 72.5% in HBV-related PAN. This is similar to the rates in vasculitis associated with ANCA.⁵³ The relapse rate in HBV-related PAN is low (<10%) compared with non-HBV-related PAN (19.4% to 57% relapse rates).^{24,49} Delayed diagnosis (>3 months) increases the risk of relapse but does not affect mortality risk.⁵⁴ Seroconversion rates from hepatitis B e-antigen positive to hepatitis B e-antibody positive (i.e., eradication of active viral infection) is achieved in just under 50% of patients treated with glucocorticoids, antiviral agents, plus limited plasmapheresis.²⁴

A prognostic tool designed for use in PAN is effectively used to distinguish patients with higher or lower risk of poor outcome. This simple clinical score (the Five Factor Score), assessed at diagnosis, consists of assessment of the following abnormalities: proteinuria (<1 g/day), elevated creatinine (>1.58 mg/dL), gastrointestinal involvement, central nervous system involvement, and cardiomyopathy.⁵⁵ Allocating 1 point per item, there is a reduced survival for patients with higher scores (86% survival for 0 points, 69% survival for 1 point, 47% survival for 2 or more points) at onset when followed up for 6 years.⁵⁵ Mortality can also be predicted using the Birmingham Vasculitis Activity Score, a clinical index of disease activity.^{39,49} Older age at diagnosis has been shown to be an important adverse predictor of survival in the first year and after 5 years of follow-up.^{47,56}

COGAN'S SYNDROME

Cogan's syndrome⁵⁷ is a rare form of vasculitis. The median age at onset is 25 years.^{58,59} Patients typically present with red painful eyes and/or hearing loss concurrently or within 4 months in 75% of patients. Most patients do not develop features of more widespread systemic vasculitis, with the exception of aortitis and aneurysm or aortic insufficiency, occurring in about 12% of patients.⁶⁰ In atypical Cogan's syndrome, where the ocular manifestation is episcleritis, scleritis, iritis, uveitis, or chorioretinitis rather than interstitial keratitis, there is a worse prognosis and a higher frequency of aortic and other systemic manifestations.⁶¹ Eye symptoms usually consist of photophobia with red and irritable eyes. The audiovestibular symptoms are rapid in onset with partial or complete hearing loss (often bilateral), vertigo, and ataxia. Although the vertigo and ataxia may improve, the hearing loss is usually permanent. About 50% of cases will have constitutional features such as weight loss, fever, lymphadenopathy, hepatosplenomegaly, and purpura. Aortic involvement is the most serious manifestation of Cogan's syndrome and accounts for most deaths. Ophthalmic and audiovestibular features may precede aortic involvement by months to several years. Rarely, patients develop widespread vasculitis, with purpura and gangrene.⁶²

Pathology

A mixture of acute and chronic inflammation is present in large blood vessels, especially around the internal elastic lamina. The main findings are an infiltration of neutrophils, eosinophils, mononuclear cells, and fibrosis. Occasionally granulomas containing giant cells can be found in the lesions.

Clinical Features

The diagnosis of Cogan's syndrome is largely based on clinical features, supported by the histologic abnormalities and exclusion of other conditions. Definitive serologic markers do not exist. Most patients have leukocytosis, anemia, thrombocytosis, and an elevated sedimentation rate during active phases of their disease. Patients with aortitis show aortic root dilation and aortic insufficiency on echocardiography or magnetic resonance imaging. Rare case reports demonstrate the presence of autoantibodies such as antienothelial cell antibodies⁶³ and anti-myeloperoxidase (MPO) antibodies,⁶⁴ but their role in the disease is unknown.

Treatment

There is no clear evidence base because there are no prospective studies of treatment in this rare disease. Interstitial keratitis usually responds to topical corticosteroids. Most experts manage the acute audiovestibular symptoms with high doses of glucocorticoids, with a prompt response within a month (or none at all in resistant cases). Cytotoxic drugs,⁶⁵ methotrexate,⁶⁶ and cyclosporine⁶⁷ have been used to treat the condition. The course is variable: For some patients there is only a single episode, and they are free of active disease thereafter. The more typical course is one of waxing and waning symptoms for months or years. Most patients sustain permanent hearing loss, and almost half lose hearing entirely; by contrast, few have permanent effects on vision.⁶⁰ Cochlear implantation can successfully restore some hearing in these patients. Aortic valve replacement and surgical repair of aortic aneurysms may be required, but as in Takayasu's arteritis,⁶⁸ it would probably be best to ensure that there is no active disease at the time of surgery.

BUERGER'S DISEASE

Buerger's disease, also known as *thromboangiitis obliterans*, is an inflammatory vaso-occlusive disease that predominantly affects the vascular supply to the lower limbs in young adult male tobacco smokers, although women and older adults⁶⁹ can also be affected. The average age at onset is 35 years. Tobacco, especially cigarette smoking, is clearly important, but the mechanism of action remains unknown. There is no clear human leukocyte antigen association.⁷⁰ Antibodies directed against collagen, elastin, and laminin have been reported in some patients.^{71,72} The presence of high levels of antiendothelial cell antibodies has been described in patients with active disease, but not in patients in remission.⁷³ ANCA directed against MPO, lactoferrin, and elastase have also been associated with severe cases.⁷⁴ More

recently a link to periodontal disease and anticardiolipin antibody has been reported.⁷⁵

Pathology

In most cases Buerger's disease affects small arteries and veins in the distal extremities, but there are case reports of visceral arterial involvement including coronary, pulmonary, and mesenteric arteries. There is a transmural infiltration of polymorphonuclear leukocytes and lymphocytes with preservation of the internal elastic lamina.⁷⁶ Thrombosis is prominent, and microabscesses can be found in the vessel wall and surrounding tissue. The infiltrating cells are enriched in CD3⁺ T cells; CD68⁺ macrophages and dendritic cells have been reported to be increased during disease activity.⁷⁷

Clinical Features

Buerger's disease typically begins with bilateral pain and ischemia in both lower extremities, although the upper extremities may be the site of initial symptoms. At first, the symptoms can be mild, with paresthesia or pain on exposure to cold. Most cases evolve rapidly, however, with increasing ischemic (claudicant) limb pain, digital cyanosis, splinter hemorrhages, and skin vesicles. Digital ulcers often occur, especially after minor trauma.⁷⁸ The disease typically begins distally, with symptoms worse in the tips of the toes (and fingers), but it progresses to larger, more proximal vessels over several years. Usually Buerger's disease does not cause proximal leg claudication. Superficial phlebitis occurs in about one-third of patients and may be the first symptom. Typical angiographic changes include multiple bilateral areas of narrowing or occlusion in the digital, palmar, plantar, ulnar, radial, tibial, and peroneal arteries. Small collateral vessels around the occlusion can appear to be corkscrew shaped. More proximal lesions resemble atherosclerotic occlusion. Although these findings are typical, none are pathognomonic; in the absence of pathologic confirmation, the differential diagnosis includes premature atherosclerosis; hyperviscosity syndrome; scleroderma and other rheumatic diseases; Takayasu's arteritis; embolic disease including cholesterol emboli and atrial myxomas; ergot toxicity; and thoracic outlet syndrome.

Treatment

The most important treatment is to stop smoking. In patients who are unable to comply with this, nicotine substitutes may be used at least in the short term.⁷⁹

Affected limbs must be protected from trauma and cold. Ulcers and cellulitis often require antibiotics and local wound management. Anecdotal use of calcium channel blockers and pentoxifylline reportedly has been beneficial in some, but not all, patients. Sympathectomy seems to provide little or no long-term benefit and is not usually recommended.⁸⁰ Intravenous prostacyclin is effective and superior to aspirin⁸¹ and also superior to lumbar sympathectomy for rest pain or ischemic ulcers⁸⁰ on the basis of two large randomized controlled trials. Recent approaches using bone marrow-derived mesenchymal stem cells, basic

fibroblast growth factor, and granulocyte colony-stimulating factor have been effective in treatment of leg ulcers and ischemia in small open-label studies.⁸²⁻⁸⁵ A radical surgical approach using omental grafting is reported in large open-label surgical studies to offer more than 90% success in improving the severe ischemic complications.⁸⁶

In patients who continue to smoke, about half require amputation, often multiple times as more proximal vessels are involved.⁸⁷ If they stop smoking, most patients will stop getting worse, but a few still require amputation. However, the ischemic limb may be a source of pain and ulceration for many years.

SUSAC'S SYNDROME

This is another rare condition affecting a wide age range from children to older adults.^{88,89} The etiology is unknown. The presentation is usually with sudden onset of sensorineural hearing loss in the context of encephalopathy and branch retinal artery occlusion.⁸⁸ The differential diagnosis would include Cogan's syndrome and GPA. The pathogenetic mechanisms suggest an endotheliopathy rather than a true vasculitis. Nevertheless, treatment with immunosuppressive agents including glucocorticoids and cytotoxic agents is reported to improve some patients, but there are no controlled trials.⁸⁹ The diagnosis rests on the combination of clinical features and exclusion of other causes. The outcome is variable, but most patients recover some hearing.⁹⁰

VIRUS-INDUCED VASCULITIS

The most common virus-associated vasculitis today is HCV-associated cryoglobulinemia (see Chapter 91). The majority of patients with cryoglobulinemia have concomitant hepatitis C infection (see Chapter 91). Treatment with immunosuppressive drugs has been only moderately successful; many patients die as a result of vasculitis or liver disease. Saadoun and colleagues²⁶ describe their cohort of 72 patients treated with combination antiviral therapy. Patients responded well to a combination of interferon- α and ribavirin; however, 40% required glucocorticoids, around 12% had plasmapheresis, and 6% received immunosuppressive drugs for severe complications. The mortality was just over 10%. The vasculitis resulting from human immunodeficiency virus infection is discussed in Chapter 113. Although the most common rheumatic manifestation of parvovirus B19 infection is arthritis (see Chapter 114), some children with chronic parvovirus B19 infection have been reported to develop a vasculitis similar to PAN. It is not clear, given the high incidence of the infection in children, whether the presence of the virus is coincidental or causative in the few cases of vasculitis described.⁹¹

KEY POINTS

Vasculitis mediated by immune complexes (ICs) includes a heterogeneous group of disorders linked by inefficient or dysregulated clearance of ICs.

The most common types of IC-mediated vasculitis are hypersensitivity vasculitis, Henoch-Schönlein purpura (HSP), and mixed cryoglobulinemia. Rarer forms of this condition include hypocomplementemic urticarial vasculitis and erythema elevatum diutinum.

Connective tissue disorders such as systemic lupus erythematosus, Sjögren's syndrome, and rheumatoid arthritis can be associated with IC-mediated vasculitis.

Cutaneous involvement of small blood vessels is the most prominent feature in the majority of cases, but extracutaneous involvement occurs in some forms.

The classic cutaneous finding in small vessel vasculitis is palpable purpura, but a variety of other skin lesions may be found including pustules, vesicles, urticaria, and small ulcerations.

Direct immunofluorescence studies of involved blood vessels demonstrate characteristic types and patterns of immunoglobulin (Ig) and complement deposition.

Hypersensitivity vasculitis usually results from a reaction to a medication or an infection.

HSP is associated with purpura, arthritis, glomerulonephritis, and colicky abdominal pain. IgA deposition is found within blood vessel walls.

Cryoglobulinemic vasculitis is most often associated with long-standing hepatitis C virus infection. The term *mixed cryoglobulinemia* is sometimes used for this disorder because the immunoreactants involved in the disease include both IgG and IgM.

The inflammation within blood vessel walls that characterizes vasculitis frequently leads to cellular destruction, damage to the vascular structures, compromise of blood flow to organs, and organ dysfunction. It has been known for decades that immune complex (IC)-mediated mechanisms play critical roles in many forms of systemic vasculitis, particularly those that involve primarily small blood vessels. As described in Chapter 87, the use of horse serum and sulfonamides as therapeutic agents for infectious diseases in the early 1900s frequently led to small vessel vasculitis on the basis of serum sickness or hypersensitivity phenomena. *Hypersensitivity angitis*, often confused with the pauci-immune form of vasculitis now termed *microscopic polyangiitis* (see Chapter 89),¹ was one of five disorders included in the original classification of the vasculitides in 1952.²

Immune Complex–Mediated Small Vessel Vasculitis

JOHN H. STONE

This chapter focuses on forms of small vessel vasculitis that are mediated by IC deposition. These disorders include hypersensitivity vasculitis, Henoch-Schönlein purpura (HSP), mixed cryoglobulinemia, hypocomplementemic urticarial vasculitis, and erythema elevatum diutinum. In addition, forms of vasculitis associated with connective tissue diseases, particularly systemic lupus erythematosus (SLE), Sjögren's syndrome, and rheumatoid vasculitis, are discussed briefly. Anti-glomerular basement membrane disease and the pauci-immune forms of vasculitis such as those associated with antineutrophil cytoplasmic antibodies, are discussed elsewhere (see Chapter 89). Throughout this chapter, the terms *vasculitis* and *angitis* are used interchangeably when referring to inflammation involving small blood vessels (capillaries, venules, arterioles).

Because all forms of IC-mediated vasculitis share certain elements of pathogenesis, have many cutaneous findings in common, and have overlapping differential diagnoses, these aspects of the disorders are considered together. The epidemiology, cause, distinctive pathophysiologic mechanisms, unique clinical features, and approaches to treatment are discussed separately for each condition. Treatments are also summarized in Table 91-1.

PATHOGENESIS

Arthus Reaction

The Arthus reaction, described after the injection of horse serum into rabbits, forms the basis of our understanding of IC-mediated diseases.³ The formation of ICs in the Arthus reaction initiates complement activation and an influx of inflammatory cells, followed by thrombus formation and hemorrhagic infarction in the areas of most intense inflammation. ICs, formed by the combination of antibody and antigen, are continuously created (and usually cleared swiftly and efficiently) by the reticuloendothelial system as a means of neutralizing foreign antigens. Under some circumstances, however, ICs escape clearance and become deposited within joints, blood vessels, and other tissues, inciting inflammation and causing disease. ICs deposited in the blood vessel walls lead to vasculitis. Similarly, those deposited within small blood vessels of the kidney—the glomeruli—cause glomerulonephritis.⁴

Immunogenicity

The fate of formed ICs is governed by several major factors including antigen load, antibody response, efficiency of the reticuloendothelial system, physical properties of the blood vessels (including flow dynamics and previous endothelial

Table 91-1 Potential Treatment Approaches for Different Forms of Immune Complex–Mediated Vasculitis

Disease	Preferred Treatment Approach
Hypersensitivity vasculitis	Removal of the offending agent Brief (2- to 4-wk) course of glucocorticoids for severe cases
Henoch-Schönlein purpura	No treatment required in the majority of cases, particularly children (symptomatic therapy only) Moderate glucocorticoid doses (prednisone 20-40 mg/day) are of variable utility but may be used empirically in patients with disabling symptoms Pulse glucocorticoids (e.g., 1 g methylprednisolone/day) employed with anecdotal success for refractory purpura when moderate glucocorticoid doses have failed Refractory glomerulonephritis may require high-dose glucocorticoids, azathioprine, mycophenolate mofetil, or cyclophosphamide
Cryoglobulinemia	Combined antiviral therapies and B cell depletion strategies synergistic in treating mixed cryoglobulinemia associated with hepatitis C Rituximab possibly effective in treating idiopathic mixed cryoglobulinemia
Hypocomplementemic urticarial vasculitis	Low-dose prednisone (5-20 mg/day), hydroxychloroquine, dapsone Higher doses of glucocorticoids in patients with serious internal organ involvement or ulcerative skin lesions
Erythema elevatum diutinum	Anecdotal reports of success with tumor necrosis factor inhibition
Connective tissue disease	Dapsone or sulfapyridine
Rheumatoid vasculitis	Hydroxychloroquine, low-dose prednisone (5-20 mg/day), azathioprine High-dose glucocorticoids plus cyclophosphamide for widespread necrotizing vasculitis Anecdotal experience suggests that tumor necrosis factor inhibition or rituximab might be effective in combination with glucocorticoids

damage), and solubility of the ICs themselves. The ratio of antibody to antigen determines the solubility of ICs. Large ICs, formed when antibody and antigen are present in approximately equal proportions, are identified and removed easily by the reticuloendothelial system. In contrast, small ICs are formed in conditions of antibody excess. Small ICs remain in the serum and do not elicit an immune response within tissues. However, when there is a slight antigen excess, ICs precipitate from the serum and become trapped within certain vascular beds. Following the deposition of ICs in tissue, a cascade of pathologic events ensues: complement fixation, neutrophil recruitment, local inflammation, lysosomal release, oxygen free radical generation, and tissue injury.

CUTANEOUS MANIFESTATIONS

Small blood vessels generally include capillaries, postcapillary venules, and nonmuscular arterioles—vessels that are typically less than 50 μm in diameter. These are found principally within the superficial papillary dermis (Figure 91-1). Medium-sized blood vessels, those between 50 and 150 μm in diameter, contain muscular walls and are located principally in the deep reticular dermis, near the junction of the dermis and subcutaneous tissues. Vessels larger than 150 μm in diameter are not commonly found in the skin.

Figure 91-1, which demonstrates the location and size of blood vessels involved in various types of cutaneous vasculitis, illustrates the types of blood vessels affected by several forms of IC-mediated disease. A blood vessel's size correlates closely with its depth in the skin layers: The larger the vessel, the deeper its location. Although telltale signs of vasculitis may be evident on inspection of the skin's surface, the epidermis is avascular. Therefore the pathologic findings in cutaneous vasculitides lie within the dermis and subcutaneous tissues.

Palpable purpura, synonymous with small vessel vasculitis, is the most common cutaneous finding in IC-mediated vasculitis (Figure 91-2). Purpuric lesions result from the extravasation of erythrocytes through damaged blood vessel

walls into tissue. Many other skin manifestations are possible in these conditions including vesicles, pustules, urticaria, superficial ulcerations, nonpalpable lesions (macules and patches), and splinter hemorrhages (Figure 91-3). These lesions frequently occur in combination, and careful examination usually reveals a purpuric component. Purpuric lesions *do not blanch* when pressure is applied to the skin. Following resolution, purpuric lesions may leave postinflammatory hyperpigmentation, particularly if repeated bouts occur (see Figure 91-3F).

In IC-mediated vasculitis, purpuric lesions are usually distributed in a symmetric fashion over dependent regions of the body, particularly the lower legs, because of the increased hydrostatic pressure in these areas. Purpuric lesions are not always palpable to the touch, and the

Figure 91-1 Size of the blood vessels involved in forms of cutaneous vasculitis. The types of vasculitis with an immune complex–mediated pathogenesis include Henoch-Schönlein purpura (HSP), cutaneous leukocytoclastic angiitis (CLA), mixed cryoglobulinemia (CRYO), and connective tissue disease/rheumatoid vasculitis (CTD/RV). ANCA, anti-neutrophil cytoplasmic antibody; PAN, polyarteritis nodosa.

Figure 91-2 Hypersensitivity vasculitis. Palpable purpura in a patient with hypersensitivity vasculitis.

existence of palpable purpura does not necessarily imply an IC-mediated pathophysiology; pauci-immune forms of vasculitis such as granulomatosis with polyangiitis (GPA) (formerly Wegener's granulomatosis), microscopic polyangiitis, and Churg-Strauss syndrome, for example, may present with

identical skin findings (albeit distinctive histopathology; see Chapter 89).

PATHOLOGIC FEATURES

Full pathologic assessment of cutaneous vasculitis involves examination of a skin biopsy specimen by both light microscopy and direct immunofluorescence (DIF). DIF is a particularly critical procedure in the evaluation of small vessel vasculitides. DIF studies must be planned at the time the biopsy is performed because they require a fresh skin biopsy sample.

Light Microscopy

Figure 91-4A displays the light microscopy findings of cutaneous vasculitis. The optimal time for skin biopsy is 24 to 48 hours after the appearance of a lesion. Biopsies should be obtained from a nonulcerated site. For ulcerated lesions—usually more of an issue with medium vessel vasculitides—biopsies should be taken from the ulcer's edge. The cellular infiltrates in cutaneous vasculitis are usually made up of a combination of neutrophils and lymphocytes, but most cases demonstrate a predominance of one cell type or the other. Lymphocyte-rich infiltrates may be seen in specimens taken from either new (<12 hours) or old (>48 hours) lesions, regardless of the underlying type of vasculitis. Even in connective tissue disorders such as Sjögren's syndrome, the typical finding is a leukocytoclastic vasculitis rather than a lymphocytic vasculitis.⁵

Figure 91-4 Skin biopsy findings in immune complex-mediated small vessel vasculitis. **A**, Light microscopy. **B**, Direct immunofluorescence demonstrating IgA deposits.

The essential histologic feature in any form of cutaneous vasculitis is the disruption of blood vessel architecture by an inflammatory infiltrate within and around the vessel walls. Endothelial swelling and proliferation, leukocytoclasia (degranulation of neutrophils, leading to the production of nuclear “dust”; see [Figure 91-4](#)), and extravasation of erythrocytes may be evident in the biopsy but are not essential to the diagnosis.

Direct Immunofluorescence

Although the diagnosis of cutaneous vasculitis rests on routine histology, the features revealed by hematoxylin and eosin stains do not distinguish between pauci-immune and IC-mediated disorders. DIF studies complement the histologic information, provide the only way of diagnosing HSP with certainty, and yield important clues regarding the nature of the underlying disease. The performance of *separate* biopsies for histologic and DIF analyses is recommended if sufficient lesions exist. With DIF studies, frozen sections are incubated with fluorescein-labeled anti-human immunoglobulin (Ig) G, IgM, IgA, and C3. The staining patterns of these immunoreactants may provide insight into not only the diagnosis but also the pathophysiology of certain conditions. [Figure 91-4B](#) displays the typical DIF findings in a skin lesion from a patient with IC-mediated vasculitis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of IC-mediated small vessel vasculitis is shown in [Table 91-2](#). There are three main groups of disorders in the differential diagnosis of IC-mediated small vessel vasculitis: other forms of IC-mediated disorders, forms of small vessel vasculitis that are not mediated through

ICs, and vasculitis mimickers that involve small blood vessels. A diagnostic algorithm that includes the critical laboratory and radiographic tests is shown in [Figure 91-5](#).

CLINICAL SYNDROMES

Hypersensitivity Vasculitis (Cutaneous Leukocytoclastic Angiitis)

The term *hypersensitivity vasculitis* (see Chapter 87) generally refers to an IC-mediated small vessel vasculitis of the skin that spares internal organs and usually follows drug exposures or infections. The Chapel Hill consensus conference recommended eliminating the term *hypersensitivity vasculitis* in favor of *cutaneous leukocytoclastic angiitis* because of the disorder’s usual confinement to the skin and its predominant cell type, the neutrophil.¹ However, *hypersensitivity vasculitis* remains firmly embedded in the medical literature. The disease is characterized pathologically by IC deposition in capillaries, postcapillary venules, and arterioles. A similar illness—serum sickness—is a systemic illness that includes rash and prominent arthralgias or arthritis; it occurs 1 to 2 weeks after exposure to a drug or foreign antigen.

In 1990 the American College of Rheumatology (ACR) performed a study designed to identify features that distinguished one form of vasculitis from others.⁶ The resulting ACR classification criteria for hypersensitivity vasculitis are shown in [Table 91-3](#).⁷ The key historical element in evaluating a patient with possible hypersensitivity vasculitis is identifying exposures that may have triggered the reaction. However, in approximately half of all patients with presumed hypersensitivity vasculitis, no inciting agent can be identified.

Table 91-2 Differential Diagnosis of Immune Complex-Mediated Vasculitis

Immune Complex-Mediated Vasculitides
Hypersensitivity vasculitis

Purpura fulminans
Disseminated intravascular coagulation
Embolism
Cholesterol emboli
Atrial myxomas
Vascular wall pathology
Calciophylaxis
Amyloidosis
Infection
Infective endocarditis
Leprosy (Lucio's phenomenon)

A long list of medications, infections, and other exposures may lead to the syndrome of hypersensitivity vasculitis. The typical history for a drug-induced hypersensitivity vasculitis is the occurrence of clinical symptoms approximately 7 to 14 days after starting a new medication. Although virtually any medication can be associated with the induction of a hypersensitivity vasculitis, antibiotics (particularly penicillins and cephalosporins) are the most common offenders. Other common culprits are diuretics and antihypertensive agents, but when confronted with a patient with a potential drug-induced vasculitis it is critical to examine and potentially discontinue any medication added within a recent timeframe. Drug-induced hypersensitivity vasculitides begin to resolve within days of removal of the offending agent.

Thorough efforts are also required to exclude disease in organs other than the skin, the finding of which would implicate another form of vasculitis (see Figure 91-5). For example, although hypersensitivity vasculitis can mimic the skin features of microscopic polyangiitis, it does not involve the kidneys, lungs, peripheral nerves, or other internal organs and is not associated with antineutrophil cytoplasmic antibodies.

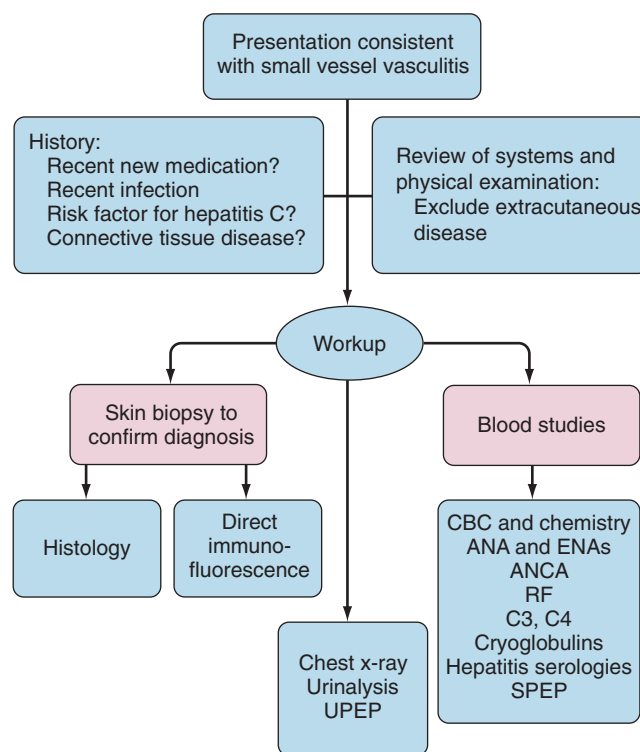

Figure 91-5 Diagnostic algorithm for immune complex-mediated small vessel vasculitis. The critical diagnostic test is usually a skin biopsy with hematoxylin and eosin staining and direct immunofluorescence. ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; CBC, complete blood count; ENA, extractable nuclear antigen; RF, rheumatoid factor; SPEP, serum protein electrophoresis; UPEP, urine protein electrophoresis.

Removal of the inciting agent is the most critical therapy for hypersensitivity vasculitis when the likely agent can be identified. In patients who have been exposed to multiple medications, determining the inciting agent may be difficult and may require the withdrawal of multiple agents simultaneously until the syndrome clears, typically in 1 to 2 weeks.

The prognosis for patients with hypersensitivity vasculitis depends on the inciting cause. Treatment with glucocorticoids is reserved for patients with extensive disease and can usually be discontinued within several weeks. Patients who experience repeated disease flares may need low-dose glucocorticoids to prevent recurrences.

Table 91-3 American College of Rheumatology 1990 Criteria* for the Classification of Hypersensitivity Vasculitis

Age >16 yr

Henoch-Schönlein Purpura

HSP is an IC-mediated form of small vessel vasculitis that is strongly associated with IgA deposition within blood vessel walls. Many cases of HSP occur after upper respiratory tract infections. Multiple bacterial, viral, and other infectious agents have been suggested as the cause of HSP, but the true cause remains unknown. The 1990 ACR criteria for the classification of HSP are shown in Table 91-4.⁸

A major risk factor for HSP (as well as IgA nephropathy, which has renal findings identical to those of HSP) is aberrant glycosylation of O-linked glycans in the hinge region of a fraction of IgA1 molecules.⁹ Rather than terminating with galactose, the aberrant galactose-deficient O-glycans end with N-acetylgalactosamine (GalNAc) or sialylated GalNAc. The terminal GalNAc moiety on the aberrantly glycosylated IgA1 may in turn be recognized by antiglycan antibodies, leading to the formation of circulating immune complexes that deposit in the skin, joints, kidneys, and other organs. However, a high serum Gd-IgA1 level is not sufficient for the development of clinical symptoms. A “second hit” in the form of another environmental or inherited risk factor is required to produce HSP. This probably explains why multiple types of infections and many different drugs (e.g., antibiotics) have been linked etiologically with HSP.

The hallmarks of HSP include an upper respiratory tract infection followed by a syndrome characterized by a purpuric rash, arthralgias, abdominal pain, and renal disease. HSP is usually viewed as a disease of childhood, and the majority of cases affect children younger than 5 years. However, adults can also be affected by HSP and have a greater tendency toward a prolonged disease course (with recurrent bouts of purpura) than do children.¹⁰ Colicky abdominal pain, presumably secondary to gastrointestinal vasculitis, is a common characteristic of HSP and frequently occurs within a week after the onset of rash. Sometimes the gastrointestinal symptoms of HSP precede the onset of purpura, leading to a diagnostic quandary and occasionally to exploratory surgery. Endoscopy may demonstrate purpura in the upper or lower intestinal tract. Mild glomerulonephritis is common and generally self-limited, although some patients develop end-stage renal disease.

In children with mild manifestations, the clinical history alone may be sufficient to confirm the diagnosis. In more serious cases (e.g., in the presence of renal involvement) or when there is sufficient doubt about the diagnosis, biopsy of an involved organ is essential. Unlike in other forms of

IC-mediated disease, however, DIF reveals florid IgA deposition. In the proper clinical setting, this finding is diagnostic of HSP. Other forms of small vessel vasculitis may have small quantities of IgA within blood vessels, but IgA is not the predominant immunoreactant in such cases.

In mild cases of HSP, no specific therapy is necessary. Even for patients with glomerulonephritis, it has been difficult to demonstrate that treatment with glucocorticoids or immunosuppressive agents significantly alters the outcome. Despite this, it is prudent to treat aggressive renal involvement with an immunosuppressive regimen including high-dose glucocorticoids and another immunosuppressive agent such as cyclophosphamide, azathioprine, or mycophenolate mofetil, depending on disease severity.

Recurrences of skin disease, often consisting of multiple episodes occurring over many months, are not unusual. However, even in patients with recurrent disease, the rule is for the disorder to subside and to resolve completely over a few months to a year. In a minority of patients, some evidence of permanent renal damage persists in the form of proteinuria and hematuria. Less than 5% of patients develop renal failure as a result of HSP.

Cryoglobulinemic Vasculitis

Cryoglobulins are immunoglobulins characterized by a tendency to precipitate from serum under conditions of cold.¹¹ Such proteins, detectable to a varying degree in a wide array of inflammatory conditions, do not always cause disease. In some patients, however, cryoglobulins bind to circulating antigen (e.g., portions of the hepatitis C virion), deposit in the walls of small and medium-sized blood vessels, and activate complement, leading to cryoglobulinemic vasculitis.

In contrast to most other forms of IC-mediated vasculitis, cryoglobulinemia tends to involve small- and medium-sized blood vessels. Thus the syndrome of cryoglobulinemic vasculitis can be associated with the development of large cutaneous ulcers, digital ischemia, and livedo racemosa—findings characteristic of disturbances in medium-sized vessels. The Chapel Hill Consensus Conference provided a consensus definition for mixed cryoglobulinemia (Table 91-5).¹

Three major types of cryoglobulinemia are recognized, defined by the specific kinds of immunoglobulins with which they are associated (Table 91-6). Type I, characterized by a monoclonal gammopathy (generally IgG or IgM), differs substantially from types II and III in its clinical presentation and disease associations. Type I cryoglobulinemia, associated with Waldenström’s macroglobulinemia or, less frequently, multiple myeloma, is more likely to cause syndromes related to hyperviscosity (dizziness, confusion, headache, and stroke) than necrotizing vasculitis. In contrast to the monoclonal nature of type I cryoglobulinemia, types II and III are known as *mixed cryoglobulinemias* because they are composed of both IgG and IgM. In type II cryoglobulinemia, more than 90% of cases are caused by hepatitis C infection and the cryoproteins consist of monoclonal IgM and polyclonal IgG. Cases of type II cryoglobulinemia not associated with hepatitis C are sometimes termed *mixed essential cryoglobulinemia* because their cause is not known. Type III cryoglobulinemia, typically associated with polyclonal IgG and polyclonal IgM, is associated with many

forms of chronic inflammation including infection and autoimmune disease.

Type II and III cryoglobulinemias often present with a triad of signs and symptoms: purpura, arthralgias, and myalgias. The purpura may be extensive and confluent (Figure 91-6), sometimes involving the trunk, upper extremities, and even the face; in most cases, however, the rash is confined to the lower extremities. Other organ systems commonly involved in mixed cryoglobulinemia are the kidneys and peripheral nerves. Mixed cryoglobulinemia may cause membranoproliferative glomerulonephritis that resembles lupus nephritis histopathologically. It may also cause a vasculitic neuropathy, usually with sensory symptoms predominating over motor symptoms. Finally, in rare cases, cryoglobulinemia is associated with alveolar hemorrhage.

Skin biopsy is the most straightforward method of confirming the diagnosis. Light microscopy of purpuric lesions demonstrates leukocytoclastic vasculitis. In addition, DIF studies reveal various types of immunoglobulin and complement deposition, depending on the type. In type II cryoglobulinemia, for example, DIF reveals IgG and IgM deposition, as well as complement components. Serologic testing may also yield clues to the presence of mixed cryoglobulinemia. To assay for serum cryoglobulins, the blood is collected in a prewarmed apparatus, allowed to clot at 37° C before processing, and then refrigerated at 4° C for several days. The percentage of the serum occupied by the

**Figure 91-6** Confluent purpura in mixed cryoglobulinemia. Extensive purpuric lesions are often so numerous that they form confluent areas of cutaneous involvement.

cryoprecipitate is referred to as the “cryocrit.” The difficulties involved in performing cryoglobulin assays often lead to false-negative results. Nonspecific serologic testing may also implicate mixed cryoglobulinemia. As noted, cryoglobulins detected are not always associated with disease.

A strong clue is the presence of an extremely low level of C4, reduced out of proportion to C3. In addition, the monoclonal component of type II cryoglobulins almost invariably has rheumatoid factor activity (i.e., binds to the Fc portion of IgG). Thus essentially all patients with type II cryoglobulinemia have high titers of rheumatoid factor. As markers of clinical disease activity, C4 levels, rheumatoid factor titers, and cryocrits all fare poorly, often remaining abnormal in the face of clinically improved disease.

Treatment of cryoglobulinemia has seen substantial progress in recent years. Until recently, antiviral therapies with the combination of interferon- α and ribavirin were believed to be the optimal treatment for mixed cryoglobulinemia. Dual strategies that combine antiviral therapies and B cell depletion approaches with rituximab appear to be synergistic in treating this condition and leading to long-term treatment responses.¹² The rationale behind rituximab use in cryoglobulinemia is that peripheral B lymphocyte depletion will lead to a reduction in plasma cells that produce cryoglobulins. Studies of these treatment modalities have suggested that disease relapses are associated with the absence of virologic control and peripheral B cell recovery, implying

Table 91-6 Types of Cryoglobulins

Cryoglobulin	RF Positivity	Monoclonality	Associated Diseases
Type I	No	Yes (IgG or IgM)	Hematopoietic malignancy (multiple myeloma, Waldenström's macroglobulinemia)
Type II	Yes	Yes (polyclonal IgG, monoclonal IgM)	Hepatitis C Other infection Sjögren's syndrome SLE
Type III	Yes	No (polyclonal IgG and IgM)	Hepatitis C Other infection Sjögren's syndrome SLE

Ig, immunoglobulin; RF, rheumatoid factor; SLE, systemic lupus erythematosus.

the need to combine the two treatment strategies. The optimal timing of antiviral and B cell depletion strategies is not clear. However, one reasonable approach is to initiate antiviral strategies first and then to employ rituximab within several weeks. Patients who present with overwhelming illness such as the unusual patient with alveolar hemorrhage or with symptoms of hyperviscosity are candidates for plasma exchange, with the goal of removing the pathogenic immune complexes as quickly as possible. One approach is to perform plasma exchange every other day with concomitant immunosuppressive therapy or B cell depletion for a total of seven exchanges or until there is sufficient clinical improvement. The prognosis of patients with cryoglobulinemia generally depends on the underlying cause. The outcome of type I cryoglobulinemia relates closely to the success in treating the cause. Type II or III cryoglobulinemia secondary to hepatitis C can be treated effectively if the viral infection is responsive to therapy. If patients do not tolerate antiviral therapy well or if the treatment is ineffective, they may require low to moderate doses of prednisone to control the disease.

Hypocomplementemic Urticarial Vasculitis

In contrast to common urticaria, the lesions of urticarial vasculitis (UV) last more than 48 hours, do not blanch when pressure is applied to the skin, and may leave postinflammatory hyperpigmentation. Unlike common urticaria, the lesions of UV are frequently associated with moderate pain, burning, and tenderness in addition to pruritus. Whereas common urticaria typically resolves completely within 24 to 48 hours, the lesions of UV may take days to resolve completely, often leaving residual hyperpigmentation; they may worsen without therapy.

Three different syndromes of UV are recognized: normocomplementemic UV, hypocomplementemic UV, and the hypocomplementemic urticarial vasculitis syndrome (HUVS). Normocomplementemic UV is typically a self-limited subset of hypersensitivity vasculitis. In chronic cases, normocomplementemic UV must be distinguished carefully from neutrophilic urticaria, a persistent form of urticaria not associated with vasculitis. In contrast, hypocomplementemic UV is more likely to be a chronic disorder that has certain overlapping features with SLE: low serum complements, autoantibodies, and an interface dermatitis characterized by immunoreactant deposition (complement and immunoglobulins) at the dermal-epidermal junction in a pattern essentially identical to the lupus band test. Finally, HUVS is a severe form of the disease associated with extra-cutaneous disease and an array of organ system findings atypical of SLE.¹³ For example, HUVS may be associated with uveitis, chronic obstructive pulmonary disease (COPD), and angioedema.

The skin lesions in UV tend to be centripetal, favoring the trunk and proximal extremities more than dependent regions. The lesions are painful and associated with a burning sensation rather than the pruritus of common urticaria. Biopsy of an urticarial wheal in UV demonstrates evidence of leukocytoclastic vasculitis including injury to the endothelial cells of the postcapillary venules, erythrocyte extravasation, leukocytoclasia, fibrin deposition, and a perivascular neutrophilic (or, less commonly, lymphocytic)

infiltrate. DIF demonstrates IC deposition around blood vessels in the superficial dermis and a striking deposition of immunoglobulins and complement along the dermal-epidermal junction. In the proper setting, these findings (interface dermatitis and immunoreactant deposition within blood vessels) are diagnostic of hypocomplementemic UV. HUVS, in contrast, is a clinical diagnosis based on the presence of UV and the occurrence of typical features in extra-cutaneous organ systems.

Some cases of hypocomplementemic UV respond to therapies commonly used for the treatment of SLE including low-dose prednisone, hydroxychloroquine, dapsone, or other immunomodulatory agents. Serious cases of HUVS, particularly those presenting with glomerulonephritis or other forms of serious organ involvement, may require high doses of glucocorticoids or biologic agents such as inhibitors of tumor necrosis factor. Both COPD and cardiac valve abnormalities are associated with HUVS and may require specific treatment as well.

The prognosis of UV is linked to the disorder with which it is associated. SLE, COPD, angioedema, and valvular abnormalities are all known to occur in association with this disorder and may strongly influence both quality and quantity of life.

Erythema Elevatum Diutinum

Erythema elevatum diutinum (EED) is a rare, distinctive form of leukocytoclastic vasculitis limited to the skin.¹⁴ The disorder is distinctive because of the unusual distribution of skin lesions (found symmetrically over the extensor surfaces of joints) and the prompt response to sulfone medications. The cutaneous findings are typical of any small vessel vasculitis, with a predominance of papules, plaques, and nodules. Early lesions are often pink or yellowish and then become red or purple (Figure 91-7). The natural history of untreated lesions is to persist for years, becoming doughy or hard with time. The lesions have a predilection for the skin overlying the small joints of the hands and the knees; they can also affect the buttocks. The trunk is generally spared.

The principal histopathologic findings of EED are leukocytoclastic vasculitis with fibrinoid necrosis. Although an IC basis is suspected in this disorder, DIF studies are not distinctive. EED has been associated with various connective tissue diseases (CTDs), rheumatoid arthritis, other forms of vasculitis such as GPA, human immunodeficiency virus infections, and paraproteinemias (particularly IgA). EED typically responds promptly to dapsone or sulfapyridine, but chronic therapy may be required because skin lesions recur after cessation of treatment.

Connective Tissue Disease-Associated Vasculitis

Vasculitis rarely occurs in CTDs without overt manifestations of the underlying disorder. The forms of CTD typically complicated by vasculitis include those related to SLE: lupus itself, mixed CTD, Sjögren's syndrome, and overlap CTD. Although vasculitis clearly occurs in some CTD settings, it is commonly overdiagnosed to explain perplexing disease features in patients with known rheumatic illnesses. For example, neuropsychiatric SLE is generally not caused

Figure 91-7 Erythema elevatum diutinum. Nodules typically form over the extensor surfaces of the knuckles and other joints.

by a true vasculitis but rather by other mechanisms that remain poorly defined. Whenever possible, the clinical hypothesis of vasculitis should be confirmed by biopsy.

Cutaneous vasculitis in CTDs is associated almost invariably with hypocomplementemia and high titers of antinuclear antibodies (ANAs). DIF examination of skin lesions shows granular IgG and C3 deposition in and around dermal vessels, with or without IgM, reflecting the contribution of ICs to disease pathogenesis. The phenomenon of the “in vivo ANA” is also observed in keratinocytes and dermal cells in DIF studies (Figure 91-8).

Vasculitis in patients with SLE-related disorders is more likely than other forms of vasculitis to be associated with a lymphocytic predominance. One variant of CTD-associated cutaneous vasculitis, the so-called benign

Figure 91-8 Direct immunofluorescence study in connective tissue disease-associated vasculitis, revealing tissue deposits of IgG and an “in vivo antinuclear antibody” phenomenon. This phenomenon is caused by the binding of immunoreactants to targets within the nuclei of epidermal cells.

hypergammaglobulinemia of Waldenström, is usually a true lymphocytic vasculitis. Patients with this disorder invariably have anti-Ro antibodies, and many have subclinical Sjögren’s syndrome. Lymphocytic vasculitis typically demonstrates less disruption of blood vessel architecture than does leukocytoclastic vasculitis, perhaps because lymphocytes contain fewer of the destructive enzymes found within neutrophil granules. Fibrinoid necrosis, for example, is rare in lymphocytic vasculitis. True lymphocytic vasculitis is nearly always confined to the small blood vessels of the superficial papillary dermis. Even in Sjögren’s syndrome, however, the histopathology encountered in most cases is that of leukocytoclastic vasculitis.

Rheumatoid Vasculitis

Rheumatoid vasculitis (RV) must be distinguished from the isolated digital (periungual) vasculitis that, in the absence of severe involvement, does not require intensive, vasculitis-specific therapy. Isolated digital vasculitis in patients with rheumatoid arthritis, characterized by splinter-like lesions in the periungual region (Bywaters’ lesions), is not necessarily associated with a poorer prognosis than rheumatoid arthritis without digital vasculitic lesions and does not require specific therapy for vasculitis. In contrast, RV is a potentially devastating complication that may involve both medium and small blood vessels and requires the most aggressive therapeutic interventions. Many clinical manifestations of RV are indistinguishable from polyarteritis nodosa, although microaneurysms are less common in RV. RV classically occurs in patients with nodular, rheumatoid factor–positive, joint-destructive disease who have few clinical indications of active synovitis at the time vasculitis begins. However, RV occasionally complicates early disease.

The most common presentation of RV includes purpuric lesions with or without evidence of concomitant medium vessel vasculitis. DIF examination of the skin lesions shows granular IgM and C3 deposition in vessels, consistent with an IC-mediated pathophysiology in which rheumatoid factor, complement, and cryoglobulins may all participate. Deep cutaneous ulcers near the malleoli are a hallmark of RV and require scrupulous local care, as well as judicious immunosuppression. Mononeuritis multiplex often complicates RV. High-dose glucocorticoids, tumor necrosis factor inhibitors, rituximab, and cyclophosphamide have been employed in the treatment of rheumatoid vasculitis.

Primary Angiitis of the Central Nervous System

RULA A. HAJJ-ALI • CAROL A. LANGFORD

KEY POINTS

Primary angiitis of the central nervous system (PACNS) is defined as vasculitis that is confined only to the brain, meninges, or spinal cord.

PACNS consists of subsets including granulomatous angiitis of the central nervous system (GACNS) and atypical PACNS that are differentiated by unique histologic and imaging characteristics.

The diagnosis of PACNS is based on compatible clinical features together with evidence from spinal fluid, brain and vascular imaging, and often brain biopsy.

Ruling out mimics that have a similar clinical or angiographic appearance is central to the diagnosis of PACNS.

Reversible cerebral vasoconstriction syndrome (RCVS) is among the most important mimics of PACNS that has treatment and outcome implications.

Initial treatment of PACNS includes glucocorticoids either alone or in combination with cyclophosphamide based on the subset and severity of neurologic disease.

Outcome of PACNS is variable, with the highest rate of disability and mortality being seen in GACNS.

EPIDEMIOLOGY

KEY POINTS

The incidence of PACNS is estimated at 2.4 cases per 1 million person-years.

PACNS occurs more commonly in men than women at a ratio of 2:1.

The average age of patients with PACNS is 50 years.

Vasculitis affecting the central nervous system (CNS) most commonly occurs as a manifestation of a primary systemic vasculitis or as a secondary vasculitis in settings such as connective tissue diseases or infections. When the disease is confined only to the CNS (brain, meninges, and the spinal cord), it is referred to as *primary angiitis of the central nervous system* (PACNS).

PACNS is a rare disease, first reported as a distinct clinical pathologic entity in 1959 by Cravioto and Feigin.¹ The disease was initially described as “noninfectious granulomatous angiitis with a predilection for the nervous system” that is fatal. Other reports of similar clinicopathologic phenotypes emerged in the literature, and “granulomatous angiitis of the central nervous system” was proposed to describe this

entity.^{2,3} Subsequently, different terms surfaced in the literature such as *isolated angiitis of the CNS* to encompass cases that were characterized by nongranulomatous pathologic findings.⁴ Currently, PACNS is a well-accepted terminology of this disease that emphasizes the sole involvement of the CNS.^{5,6} Following the description of diagnostic criteria for PACNS proposed by Calabrese and Mallek in 1988⁵ and the potential for effective treatment,⁷ there was a tremendous increase of published cases in the literature such that more than 500 cases have now been described worldwide.^{8,9}

Because of its rarity and our evolving understanding of PACNS, the true incidence of PACNS is difficult to calculate.⁹ In the recent era, the estimated annual incidence rate of PACNS is 2.4 cases per 1 million person-years.⁹ Middle-aged men are often affected by PACNS with a median age at onset of approximately 50 years with a male-to-female ratio of around 2:1.^{5,6,9}

GENETICS

The pathogenesis of PACNS is not well understood. To date, there has been no evidence to suggest a genetic predisposition, although this remains under active investigation.

CLINICAL FEATURES

KEY POINTS

PACNS is divided into subsets that include granulomatous angiitis of the central nervous system (GACNS) and atypical PACNS.

Masslike lesions can occur in PACNS.

Clinical features of GACNS typically include chronic insidious headaches along with diffuse and focal neurologic deficits.

Great progress has been made toward understanding the clinical features of PACNS despite the many challenges that include the lack of highly specific diagnostic modalities, the sparse material for research, and the lack of controlled clinical trials. In the recent era, specific clinical and pathologic subsets of PACNS that have prognostic implications have been identified.¹⁰⁻¹³

Proposed Criteria for Primary Angiitis of the Central Nervous System

In 1988 Calabrese and Mallek⁵ proposed diagnostic criteria for PACNS that emphasized the importance of ruling out

mimics when diagnosing PACNS. These criteria include (1) the presence of an unexplained neurologic deficit after thorough clinical and laboratory evaluation; (2) documentation by cerebral angiography and/or tissue examination of an arteritic process within the central nervous system; and (3) no evidence of a systemic vasculitis or any other condition to which the angiographic or pathologic features could be secondary.

In 2009 Birnbaum and Hellmann¹² proposed changes to the criteria described by Calabrese and colleagues, incorporating the levels of diagnostic certainty in their assessment. They proposed the term *definite diagnosis of PACNS* if there is confirmation of vasculitis on tissue biopsy and a *probable diagnosis of PACNS* when the diagnosis is based on high probability findings on an angiogram in the absence of tissue confirmation but with consideration of cerebrospinal fluid (CSF) profiles and neurologic symptoms to discriminate between PACNS and its mimics.

Although the original criteria by Calabrese served as a platform of literature-based research, their interpretation has changed fundamentally as advancement of our diagnostic modalities has revealed many unexplained neurologic diseases. The importance of ruling out mimics of PACNS remains essential in the diagnostic approach of patients with suspected PACNS.

Clinical Subsets

The original pathologic reports of PACNS as a granulomatous angiitis imposed a histologic-based nomenclature on the disease that led to the original name of *granulomatous angiitis of the CNS* (GACNS). Until the 1980s, PACNS was considered largely a homogeneous entity with a uniform clinical picture and grave prognosis. This paradigm was challenged with the introduction of direct vascular imaging as a diagnostic tool and recognition that nongranulomatous pathologic findings occur in PACNS.

Initial attempts at subclassification of PACNS described three broad subsets: GACNS, benign angiopathy of the CNS (BACNS), and “atypical” PACNS.¹⁴ BACNS has since become recognized to be a part of the reversible cerebral vasoconstriction syndrome (RCVS)¹¹ with the other PACNS subsets now being defined by pathologic or radiographic features.

Granulomatous Angiitis of the Central Nervous System

GACNS is a subset of PACNS described as a clinicopathologic entity characterized by granulomatous angiitis confined to the brain. This is a rare subset of PACNS, in which patients clinically present with chronic insidious headaches along with diffuse and focal neurologic deficits. Because the disease is confined to the brain, meninges, or the spinal cord, signs and symptoms of systemic inflammatory diseases are usually lacking. The diagnosis of this subset is confirmed by the findings of granulomatous angiitis on pathology (Figure 92-1). Typically the CSF findings include those of an aseptic meningitis picture with negative staining for microorganisms. GACNS predominantly affects middle-aged men. The most common findings on neuroimaging include infarcts, most often bilateral, as well as high-

Figure 92-1 Histopathologic findings of patients with granulomatous angiitis of the central nervous system vasculitis.

intensity T2-weighted fluid attenuation inversion recovery (FLAIR) lesions on magnetic resonance imaging (MRI) in the subcortical white matter and deep gray matter. Cerebral angiogram is not the diagnostic modality of choice given its poor spatial resolution of detecting small vessel vasculitis, which mainly occurs in GACNS.

Atypical Central Nervous System Vasculitis

This subset of PACNS comprises multiple manifestations of PACNS that are clinically, radiologically, or pathologically distinct from GACNS. Atypical PACNS represents the most frequent and heterogeneous subset of PACNS. Included in this subset are patients with specific presentations such as lesions or those with pathologic findings of lymphocytic infiltration rather than granulomatous angiitis.

Masslike Presentation. Masslike (ML) presentation is a rare manifestation of PACNS occurring in less than 5% of the cases. This presentation has gained attention after the recent report of a series of 38 patients with histologically confirmed PACNS that presented with a solitary cerebral mass.¹⁵ Typically the diagnosis is unanticipated and is confirmed after the pathologic examination from either biopsy samples or surgical excision of the mass. Unfortunately, there are no specific features on clinical assessment, neuroimaging, cerebral angiography, or CSF examination that could reliably distinguish ML-PACNS from other, more common causes of a solitary cerebral mass. Appropriate stains and cultures to rule out mycobacterial, fungal, or other infections and immunohistochemistry/gene rearrangement studies to exclude lymphoproliferative disease are essential to secure the diagnosis and exclude concomitant infectious or malignant processes.

Cerebral Amyloid Angiitis. Amyloid protein, in particular amyloid- β peptide, a fragment of the amyloid precursor peptide, can deposit in the brain, causing disease ranging from Alzheimer's disease to cerebral amyloid angiopathy (CAA). CAA-related inflammation and angiocentric inflammatory reaction in CAA is referred to as

amyloid- β -related angiitis (ABRA).¹⁶ Patients with ABRA tend to be older and more prone to hallucinations and mental status changes than other PACNS patients. MRI cannot distinguish between ABRA and other forms of PACNS, although there is a higher occurrence of cerebral hemorrhage in ABRA. ABRA carries a poor outcome, which could be related to older age and comorbidities.

Angiographically Defined Central Nervous System Vasculitis. The poor specificity of the cerebral angiogram poses a major challenge in the diagnosis of PACNS. When the diagnosis of PACNS is based on angiographic findings, a thorough evaluation should be performed to rule out mimics, especially RCVS.^{17,18}

Spinal Cord Presentation. Spinal cord presentation of PACNS is a rare subset in which disease is present only in the spinal cord. The diagnosis is usually made by biopsy.¹⁹

Nongranulomatous PACNS. Pathologic findings of lymphocytic infiltration rather than granulomatous findings can occur in PACNS. In this category, the emphasis should be in ruling out secondary causes of CNS vasculitis such as infectious or lymphoproliferative diseases; adequate staining and immunophenotyping should always be carefully carried out in this category.

DIAGNOSIS AND DIAGNOSTIC TESTS

KEY POINTS

Spinal fluid, brain and vascular imaging, and brain biopsy are central to the diagnosis of PACNS and in ruling out other diseases.

In PACNS 80% to 90% of patients have abnormal spinal fluid.

Abnormalities on cerebral angiogram are not specific for PACNS and can be seen in a wide range of other settings.

Reversible cerebral vasoconstriction syndrome is an important mimic of PACNS characterized by thunderclap headaches, normal CSF, and abnormal cerebral angiogram in which the changes resolve within 12 weeks.

Other important entities in the differential of PACNS include infection, lymphoproliferative disease, primary systemic vasculitis, connective tissue disease, and thromboembolic disease.

The diagnosis of PACNS is challenging due to the nonspecific clinical presentation, the lack of highly specific laboratory and radiologic tests, and the difficulty in obtaining pathologic material.

Diagnostic Tests

Laboratory Findings

Elevation of acute phase reactants, anemia, and thrombocytosis are not typical of PACNS and, if present, should raise the possibility of a primary systemic vasculitis or other underlying disease. Laboratory testing to rule out connective tissue diseases and thromboembolic abnormalities should be performed. Infectious workup with appropriate cultures, serologies, and polymerase chain reaction testing

should be directed by clinical and diagnostic findings and host risk factors.

Cerebrospinal Fluid Analysis

CSF is an important tool in the evaluation of PACNS. Although CSF findings are nonspecific in PACNS, its value also lies in ruling out other entities. Obtaining appropriate CSF cultures, microbiologic stains, cytology, and flow cytometry are crucial in ruling infectious and neoplastic disease. Elevated protein, modest lymphocytic pleocytosis, and occasionally oligoclonal bands and elevated IgG synthesis characterize the CSF in 80% to 90% of patients with pathologically documented PACNS.^{5,20,21} The median CSF white blood cell count is around 20 cells/ μ L, and the median CSF protein is approximately 120 mg/dL.^{5,9}

Radiologic Evaluation

MRI is a sensitive modality for the diagnosis of PACNS reaching 90% to 100%.^{9,22} Abnormalities include infarcts in 50% of patients, commonly affecting the cortex and the subcortex bilaterally.^{9,23} Affected areas include subcortical white matter, followed by deep gray matter, deep white matter, and the cerebral cortex.²⁴ Hyperintense lesions on T2-weighted sequences are common but not specific for PACNS.²⁵ Other abnormalities include mass lesions in 5% of patients¹⁵; leptomeningeal enhancement in 8% of the cases⁹; and gadolinium-enhanced intracranial lesions in about one-third of patients.⁹

Cerebral vasculature imaging by catheter-directed dye angiogram or through magnetic resonance angiography (MRA) is an important modality in the diagnosis of PACNS. Alternating areas of dilatation and stenosis characterize the angiographic findings in PACNS and typically involve the vasculature on both sides but sometimes can involve single vessels.²⁶ Other angiographic features include smooth tapering of one or multiple vessels. Although cerebral angiograms may visualize abnormalities in medium-sized vessels, they have limited sensitivity to detect abnormalities in small vessels that are less than 500 μ m in diameter. Although cerebral angiography is valuable, its specificity for the diagnosis of PACNS can be as low as 25%.²⁷ The reported “typical” angiographic findings for vasculitis are not specific to PACNS and can be encountered in atherosclerosis, radiation vasculopathy, or vascular spasm.^{26,27} Moreover, cerebral angiogram carries a poor positive predictive value in the diagnosis of PACNS in that the angiographic findings seen in RCVS can be consistent with those found in PACNS.²⁸ Vascular studies should therefore be interpreted with caution and should not be considered the diagnostic “gold standard” in PACNS.

Brain Biopsy

Brain biopsy is thought to carry a low morbidity and mortality in patients with PACNS¹⁴ and is an important part of the evaluation to confirm the diagnosis and rule out mimics. When a brain biopsy is performed, an alternative diagnosis is identified in 30% to 40% of the cases.²⁹ The interpretation of the brain biopsy results should take into consideration the potential for false-negative results because of the

patchy degree of involvement and the small amount of tissue that can often be obtained. The finding of vasculitis on pathologic examination does not exclude the diagnosis of infection or malignancy, and appropriate stains and markers should be pursued for accurate diagnosis.

Differential Diagnosis

The differential diagnosis algorithm of PACNS is large due to the lack of highly specific clinical features, laboratory, or imaging findings (Table 92-1). Excluding other entities that can have similar findings is critical in confirming a diagnosis of PACNS. Certain disease categories in particular should be considered and warrant further detailed discussion.

Reversible Cerebral Vasoconstriction Syndromes

RCVS is the leading mimic of PACNS, which is important to distinguish because it carries different implications for treatment and outcome (Table 92-2). RCVS comprises a group of disorders characterized by acute-onset headaches and reversible cerebrovasoconstriction.¹¹ These disorders include Call-Fleming syndrome, drug-induced angiopathy, migraine angiitis, BACNS, postpartum angiopathy, and drug-induced vasospasm. The clinical features of RCVS include acute onset of severe headaches, with or without neurologic deficit, with evidence of cerebral vasoconstriction that is reversible. The headaches are usually recurrent thunderclap headaches and can be precipitated by straining and coughing. RCVS can be associated with strokes (39%), generalized tonic-clonic seizures (17%), convexity subarachnoid hemorrhage (34%), lobar hemorrhage (20%), and brain edema (38%).¹⁸ RCVS occurs more frequently in women than men. In contrast to PACNS, CSF analysis is generally normal in RCVS except where there is a concomitant disorder or subarachnoid bleeding. The diagnosis of RCVS is usually brought into consideration when cerebral vascular imaging reveals multiple areas of smooth or tapered arterial narrowing followed by segments of normal-caliber or distended arteries. Typically, arterial narrowing involves multiple intracerebral arteries and their branches in both hemispheres resulting in severe arterial narrowing. The diagnosis of RCVS is secured when repeat vascular imaging reveals reversibility of the cerebral vascular abnormalities, often occurring in about 6 to 12 weeks, which is in contrast to the fixed angiographic abnormalities encountered in PACNS. There is a lack of controlled trials to direct treatment of RCVS. Calcium channel blockers are used for symptomatic treatment of the headaches, with no evidence that they alter the clinical outcome. Some experts use glucocorticoid therapy but with no evidence that this improves the outcome.

Primary Systemic Vasculitides

Primary systemic vasculitides such as granulomatosis with polyangiitis (GPA) (formerly Wegener's granulomatosis), microscopic polyangiitis, Churg-Strauss syndrome (CSS), polyarteritis nodosa, or Behçet syndrome (BS) can affect the CNS leading to inflammation and vasculitis. In GPA, CNS disease occurs in 7% to 11% of patients and presents

Table 92-2 Differentiating Clinical and Radiological Features between Reversible Cerebral Vasoconstrictive Syndrome (RCVS) and Primary Angiitis of the Central Nervous System (PACNS)

Feature	RCVS	PACNS
Gender	Female predominant	Male predominant
Cerebrospinal fluid	Normal	Abnormal
Normal magnetic resonance image	10%-15%	Very rare
Abnormal angiogram	100%	40%-50%
Headache pattern	Recurrent thunderclap	Insidious, chronic
Infarct pattern	Watershed	Small, scattered
Lobar hemorrhage	Common	Extremely rare
Convexity subarachnoid hemorrhage	Common	Very rare

in three different ways: direct invasion of granuloma from extracranial sites, remote intracranial granuloma, and rarely because of CNS vasculitis.³⁰ The diagnosis of CNS vasculitis is often made on the basis of radiologic findings and by exclusion of other etiologies of the neurologic deficits, especially infection.³¹ As in GPA, the diagnosis of CNS vasculitis in CSS is often presumed without a histologic confirmation when other mimics are excluded. Neuro-ophthalmologic manifestations including amaurosis fugax, superior oblique palsy, ischemic optic neuropathy, fourth cranial palsy, and scattered areas of retinal infarction are common presentations of CNS vasculitis in CSS.^{32,33} In BS, CNS involvement occurs in 14% of cases manifesting as meningoencephalitis involving the brain stem and rarely as a consequence of thrombosis and inflammation of the dural venous sinuses.³⁴⁻³⁶ Pathologic evaluation in neuro-BS typically shows a mononuclear infiltration around the small vessels of the brain including the venous system, which is not a typical finding in PACNS.³⁷ True CNS vasculitis rarely occurs in BS.³⁸

Connective Tissue Diseases

The brain is a common target in connective tissue diseases. In systemic lupus erythematosus (SLE), CNS involvement occurs in 14% to 80% of adults and 22% to 95% of children.³⁹ Multifocal microinfarcts, cortical atrophy, gross infarcts, hemorrhage, ischemic demyelination, and patchy multiple-sclerosis-like demyelination are typical findings in neuropsychiatric lupus. The most common microscopic brain finding in SLE is microvasculopathy, described as “healed vasculitis” consistent with hyalinization, thickening, and thrombus formation.^{40,41} Rheumatoid arthritis, Sjögren’s syndrome, and mixed connective tissue disease rarely affect the CNS in a vasculitic pattern.⁴² CNS vasculitis is typically a late occurrence in these diseases.

Infections

Infections are one of the most important entities that should be ruled out when considering PACNS. Vasculitis can occur

in the setting of human immunodeficiency syndrome (HIV), often presenting as multifocal cerebral ischemia with pathologic findings of angiocentric lymphoproliferative lesions.⁴³ In addition, HIV can result in granulomatous arteritis⁴⁴ or can affect the brain secondary to co-infections such as syphilis. *Treponema pallidum* infection can affect vessels in the subarachnoid space and result in thrombosis, ischemia, and infarction that can mimic PACNS.⁴⁵ Other infectious agents that have predilection to brain include varicella-zoster virus (VZV). VZV affects the brain either by involvement of large cerebral vessels, often affecting the proximal segments of the anterior and middle cerebral arteries in immunocompetent individuals, or small vessel disease in immunocompromised patients.⁴⁶ History of VZV rash is usually elicited before the CNS involvement but not always. The diagnosis of VZV angiitis is confirmed by finding VZV DNA in CSF or the presence of reduced serum/CSF ratios of VZV immunoglobulin G (IgG).⁴⁷ Tuberculosis affecting the CNS is an important cause of CNS vasculitis in endemic areas and should be carefully excluded. Hepatitis C,⁴⁸ West Nile virus,⁴⁹ parvovirus B19,⁵⁰ and rarely herpes simplex virus⁵¹ can cause CNS vasculitis. Cytomegalovirus can cause CNS vasculitis as an opportunistic infection in immunocompromised individuals.⁵² Rarely cysticercosis can involve middle-sized cerebral arteries.⁵³ A travel history and history of exposures are important features of the workup of patients with suspected PACNS.

Lymphoproliferative Diseases

Lymphoproliferative disease with predilection to the vascular wall such as lymphomatoid granulomatosis (LG) can cause CNS vasculitis leading to multiple small cortical infarcts and pathologic findings of multifocal angiocentric, angiodestructive lymphoma.⁵⁴ Concomitant HIV infection is common with LG and should be ruled out.⁵⁵ Rarely, LG is associated with other systemic autoimmune diseases such as Sjögren’s syndrome.⁵⁶ Other lymphoproliferative diseases such as CNS lymphoma and intravascular lymphoma can mimic PACNS.

Miscellaneous

Atherosclerotic involvement of the intracerebral arteries is common and is often a consideration in the workup of PACNS. The poor specificity of the cerebral angiogram poses a major limitation in differentiating inflammatory causes from other vasculopathies. However, the lack of inflammatory changes of the CSF and the presence of multiple atherosclerotic risk factors should raise the suspicion for atherosclerotic disease. Other entities such as antiphospholipid antibody syndrome, hypercoagulable states, and thromboembolic etiologies should be carefully ruled out. The workup of PACNS should include transesophageal echocardiogram and hypercoagulable profile to rule out thromboembolic etiologies, especially in patients presenting with recurrent strokes. Other rare diseases that mimic the angiographic findings of PACNS include Moyamoya disease, small vessel arterial dissection, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), radiation vasculopathy, and thromboangiitis obliterans.⁵⁷

TREATMENT

KEY POINTS

No standardized trials have been conducted on the treatment of PACNS.

GACNS is typically treated initially with glucocorticoids and cyclophosphamide.

The treatment of PACNS subsets besides GACNS is based on the diagnostic subset and severity of neurologic impairment.

The treatment of PACNS is guided by expert opinion and reports of case series, as well as from extrapolation from controlled trials in primary systemic vasculitis. To date, there have been no controlled trials in the treatment of PACNS. Because of this, it is not possible to have a specific treatment algorithm and therapy is based on the subtype and neurologic severity.

The report of successful treatment of GACNS with a combination of cyclophosphamide and glucocorticoids led to the regular use of this regimen.⁷ Generally, patients are treated with a combination of cyclophosphamide and high-dose glucocorticoids for 3 to 6 months until remission is achieved. Then cyclophosphamide is stopped and switched to a maintenance agent following the same principles that are used in small vessel vasculitis.⁵⁸ Maintenance therapy usually consists of either azathioprine or mycophenolate mofetil and rarely methotrexate given its low CNS penetration. The duration of maintenance therapy in PACNS is not well defined.

The treatment of atypical PACNS varies highly. Multiple factors affect the treatment regimen in atypical PACNS, and the treatment is usually individualized taking into consideration the degree of the neurologic deficit and the features of the diagnosis. All atypical PACNS cases are treated with high dose of glucocorticoids initially, and the decision to add other immunosuppressive agents is individually based. ABRA and ML-PACNS are two PACNS subsets in which cyclophosphamide is considered at the outset of the treatment.

Assessing disease status and defining remission are crucial steps in the course of treatment of PACNS. Permanent deficits occurring after the initial event in PACNS should not be erroneously considered as lack of remission. Disease is considered in remission when there is stability or improvement of the clinical and radiologic features. Serial MRI should be obtained to help in the assessment of disease activity. Adjunctive therapy for osteoporosis prevention and prophylaxis for opportunistic infections should be incorporated into the treatment plan.

OUTCOME

KEY POINTS

PACNS has an estimated mortality rate of 10% to 17%.

Moderate to severe disability occurs in up to 20% of patients with PACNS.

Originally, PACNS was described as a fatal disease by Cravioto,⁷ but an improved outlook became possible following the description of treatment with glucocorticoids and cyclophosphamide. From recent reports, the estimated mortality rate of PACNS varies between 10% and 17%^{9,59} with one study finding that survival correlated with the initial findings of infarcts and gadolinium-enhanced lesions on MRI.⁹ Salvarani and colleagues⁹ and Hajj-Ali and colleagues⁵⁹ reported that 20% of patients with PACNS had moderate to severe disability as assessed by the modified Rankin disability scores and the Barthel index, respectively. Salvarani and colleagues⁹ reported an improvement in disability scores over time.

SUMMARY

Considerable progress has been made in our understanding of PACNS. Our ability to recognize disease mimics have substantially increased our accuracy in the diagnosis of PACNS. The identification of RCVS in particular has clarified many of the cases that were erroneously diagnosed as PACNS. Effective diagnosis and management of PACNS requires a multidisciplinary team to evaluate the clinical features, obtain and interpret diagnostic tests, and determine the most effective regimen that will treat the underlying disease and minimize therapeutic toxicity.

There remains a great need for controlled trials to further guide treatment for patients with PACNS in their initial and maintenance phases. Prospective evaluation of long-term cohorts is necessary to better determine the rates of disability and long-term outcome of PACNS.

Behçet's Disease

WILLIAM S. KAUFMAN •
ELIZABETH KAUFMAN McNAMARA •
JOSEPH L. JORIZZO

KEY POINTS

Behçet's disease is a complex multisystem disease characterized by oral and genital ulcers and other systemic features.

Diagnosis is based on the International Criteria for Behçet's Disease including oral aphthae, genital aphthae, ocular lesions, cutaneous lesions, and a positive pathergy test.

Cutaneous lesions should display a neutrophilic vascular reaction on histopathologic examination.

Treatment is based on the degree of systemic involvement and ranges from topical corticosteroids to thalidomide to systemic immunosuppressive agents and tumor necrosis factor inhibitors.

Prognosis is variable, and patients typically have periods of exacerbations and remissions.

Behçet's disease is a chronic, complex multisystem disease characterized clinically by oral aphthae, genital aphthae, cutaneous lesions, and ophthalmic, neurologic, or rheumatologic manifestations. The first description of Behçet's disease was probably by Hippocrates in the fifth century BC,¹ and the first modern account was presented in 1937 by the Turkish dermatologist Hulusi Behçet, who reported on a patient with recurrent oral and genital aphthae and uveitis.²

EPIDEMIOLOGY

Behçet's disease is seen worldwide, with the highest prevalence reported in Turkey (80 to 370 patients per 100,000 inhabitants)³ and Japan (13.6 per 100,000).⁴ The prevalence and often the severity is increased in the Middle East and the Mediterranean (i.e., the "Silk Route").^{5,6} The remainder of the Asian continent has a prevalence of 7 to 30 patients per 100,000 inhabitants.⁷ It is relatively uncommon in northern Europe (0.27 to 1.18 per 100,000 inhabitants) and the United States (0.12 to 0.33 patients per 100,000 inhabitants).^{3,5,7} Patients commonly fulfill the diagnostic criteria in their mid-20s to 30s.⁸ In the past, Behçet's disease was thought to predominantly affect males, but current epidemiologic data show a more equal male-to-female ratio.⁹ Overall, the male-to-female ratio has decreased over the past 20 years with males being more affected in the Middle East and a female predominance existing in Korea, China, the United States, and northern Europe.⁷

CAUSE AND PATHOGENESIS

Although the pathogenesis of Behçet's disease remains unclear, many factors have been implicated. Heredity,

immunologic factors, infectious agents, inflammatory mediators, and clotting factors likely contribute.

Genetics

The onset of Behçet's disease is believed to be sporadic, though familial clustering, families with multiple affected members, has been reported. Individuals with a first-degree relative with the disease are at an increased risk of developing the disease.¹⁰ Additionally, children of individuals with Behçet's disease may have an earlier age of onset, suggesting genetic anticipation, which is due to a progressive increase in nucleotide repeats through consecutive generations.¹¹ Familial occurrence differs regionally throughout the world and is more common in Korea, Israel, Turkey, and Arab countries, compared with Japan, China, and Europe.⁷

Studies have shown a significant association between the human leukocyte antigen (HLA)-B51 and Behçet's disease.^{12,13} HLA-B51-positive patients are at an increased risk of developing Behçet's disease (odds ratio of 5.9).¹⁴ This association is more common in the Middle East, Mediterranean, and Japan, though not seen as often in Western nations. Disease prognosis also appears to be more severe in HLA-B51-positive patients.⁷ The role of HLA-B51 in Behçet's remains unclear. It may be that HLA-B51 is not directly involved in causing the disease but is closely linked to disease-related genes.¹⁵ Candidate genes have been localized to chromosome 6 and include the major histocompatibility complex class I chain-related gene A (MICA) and, more specifically, the MICA6 allele; perth block (PERB); new organization associated with HLA-B (NOB); and transporter associated with antigen processing genes (TAP).^{15,16} Other hypotheses suggest that HLA-B51 may contribute to the onset of Behçet's disease by serving as a heterologous antigen either through original antigen presentation or through viral or bacterial molecular mimicry.^{15,17} A recent genome-wide association study confirmed the HLA-B51 relationship and also identified a second, independent association within the MHC class I region.¹⁸

Although Behçet's disease has many features in common with the spondyloarthropathies, especially those associated with inflammatory bowel disease (IBD), the disorder in IBD patients generally evolves in a pattern resembling reactive arthritis, with an erosive axial arthritis; erosive arthritis and HLA-B27 are not associated with Behçet's disease.¹⁹

Immune Mechanisms

Immune mechanisms play a major role in Behçet's disease. Heat shock proteins, cytokines, alterations in neutrophil and macrophage activity, and autoimmune mechanisms

have all been implicated.¹⁵ Heat shock proteins are released in response to stress and may be involved in stimulating a T helper type 1 immune response through interaction with Toll-like receptors.²⁰ Specifically, immunoglobulin M–type, 47-kD cell surface heat shock protein against α -enolase has been identified in patients with Behçet's disease.²¹ Although most of the T lymphocytes thought to be involved in this reaction are of the $\gamma\delta$ type, the diversity of T lymphocytes seen in the disease suggests a response to multiple antigens, which may account for the various symptoms seen in Behçet's.²² Cytokines such as interleukin (IL)-1, IL-8, IL-12, IL-17, and tumor necrosis factor (TNF) seem to be involved in the pathogenesis. Although elevated cytokine levels may serve as an indicator of disease severity, it should be appreciated that plasma TNF levels may rise and fall as an acute-phase reactant along with C-reactive protein and the erythrocyte sedimentation rate.²³ The production of these proinflammatory cytokines, which are responsible for the chronic inflammation observed, may be the result of activated macrophages.^{15,24} In addition to macrophage activation, neutrophil chemotaxis and phagocytosis are increased in the lesions of Behçet's disease.^{15,25} This increased activity of neutrophils leads to tissue injury in the form of the neutrophilic vascular reaction seen in lesions such as aphthae, pustular cutaneous lesions, and erythema nodosum–like lesions. Circulating immune complexes also play a role in precipitating the characteristic neutrophilic vascular reaction.²⁶ Finally, the role of endothelial cell dysfunction in the pathogenesis of Behçet's disease has been suggested by decreased levels of prostacyclin in the serum of Behçet's disease patients. Increased nitric oxide concentrations in the serum, synovial fluid, and aqueous humor of individuals with Behçet's may play a role in endothelial activation, resulting in vascular inflammation and thrombosis.^{27,28} Elevated homocysteine levels have been cited as the cause of the increased nitric oxide concentrations, suggesting that hyperhomocysteinemia may represent an acquired risk factor for Behçet's, which is potentially reversible.^{29–31}

Infectious Agents

Several studies have suggested a role for various infectious agents in the pathogenesis of Behçet's disease; however, no organisms have been consistently isolated. Antistreptococcal antibodies have been isolated in the serum of patients with Behçet's disease.³² Higher concentrations of *Streptococcus sanguis* have also been found in the oral flora of patients with Behçet's disease and may play a role in the development of aphthae, which is often the initial manifestation.³³ In addition to streptococcal antigens, other bacteria such as *Escherichia coli* and *Staphylococcus aureus* may have a role in Behçet's disease through the activation of lymphocytes.³⁴ Additionally, a lipoprotein of *Mycoplasma fermentans* has been found in patients with Behçet's. This lipoprotein (MALP-404) contains the specific peptide motif, which is capable of being presented by HLA-B51.³⁵ Studies have also indicated that there is a higher rate of *Helicobacter pylori* cytotoxin-associated gene-A antibodies in Behçet's patients. These antibodies may cause endothelial damage via cross-reaction with endothelial antigens. *H. pylori* eradication in these patients has been shown to decrease disease severity.³⁶

Herpes simplex virus (HSV) deoxyribonucleic acid (DNA) has been isolated from the nuclei of peripheral blood lymphocytes by polymerase chain reaction (PCR) assay in patients with Behçet's disease.¹⁹ HSV has also been detected by PCR in biopsy samples of genital and intestinal ulcers of Behçet's patients.³⁴ Other studies, however, have shown no difference in the detection of HSV in Behçet's patients with and without oral aphthae.³⁷

In summary, although the cause and pathogenesis of Behçet's disease are not completely understood, they likely involve an infectious or environmental trigger and subsequent inflammatory response in a genetically predisposed individual. The article by Zouboulis and May¹⁵ provides an excellent overview of the current understanding of the pathogenesis of Behçet's disease.

CLINICAL FEATURES

Aphthae

Oral aphthae, or canker sores (Figure 93-1), are often the initial feature of Behçet's disease and constitute a requisite diagnostic feature (although many believe that Behçet's occurs in the absence of oral aphthae). Oral ulcerations usually occur in crops of more than 3 to 10s of lesions, but individual lesions may occur on the buccal mucosa, gingiva, lips, and tongue. Aphthae tend to be painful and shallow, and they heal without scarring over 1 to 3 weeks.³⁸ Genital ulcers typically occur on the scrotum and penis in males and on the vulva or vaginal mucosa in females. These aphthae are similar in appearance to oral lesions, but they have a greater tendency to scar and may recur less frequently.³⁸ Lesions in the oral mucosa are generally easy to distinguish from oral HSV, but with genital lesions, HSV should be excluded by viral culture or PCR before lesions are accepted as a diagnostic criterion.

Cutaneous Lesions

Several cutaneous manifestations of Behçet's disease have been described: erythema nodosum–like lesions, pyoderma gangrenosum–like lesions, Sweet's syndrome–like lesions, cutaneous small vessel vasculitis, and pustular vasculitic

Figure 93-1 Oral aphtha.

Figure 93-2 Pustular vasculitis lesions representing a neutrophilic vascular reaction.

lesions (Figure 93-2) including lesions induced by trauma—the so-called pathergy lesion.³⁸ Pathergy signifies the development of erythematous pustules or papules 24 to 48 hours following puncture of the skin with a 20- to 21-gauge sterile needle.³⁹ Specimens from all these lesions demonstrate a neutrophilic vascular reaction on histopathologic analysis.⁴⁰ Acneiform or pseudofolliculitis lesions should be considered nonspecific, nondiagnostic findings because of their common occurrence in acne vulgaris and folliculitis.

Ophthalmic Features

A variety of ocular manifestations have been reported in Behçet's patients including anterior and posterior uveitis, retinal vasculitis, and hypopyon, with secondary glaucoma, cataract formation, decreased visual acuity, and synechiae formation.⁴¹ Ocular involvement occurs in 83% to 95% of men and 67% to 73% of women with Behçet's disease.⁴¹ Although ocular involvement is not commonly the presenting feature of Behçet's disease, it is a major source of serious morbidity, and close ophthalmologic evaluation and follow-up are critical to prevent blindness in these patients.⁴² BenEzra and Cohen⁴³ suggested that if ocular disease does not present within a few years of diagnosis, it is unlikely to be a major problem.

Arthritis

The arthritis of Behçet's disease is typically a nonerosive, inflammatory, symmetric, or asymmetric oligoarthritis, although polyarticular and monoarticular forms are also seen. The most commonly involved joints are the knees, wrists, ankles, and elbows.⁴⁴ The prevalence of arthritis among different populations ranges from 40% to 60%, and joint erosions are not observed.⁴² Dilsen and colleagues⁴⁵ reported that 10% of patients with Behçet's disease had a sacroiliitis. However, *HLA-B27*-positive patients were not excluded from their series, and occult IBD was not excluded, as required by O'Duffy and Goldstein.⁴⁶ Other studies have shown no significant difference in the occurrence of sacroiliitis between patients with Behçet's disease and the normal population. *HLA-B27*-positive patients with erosive sacroiliitis should be included in the reactive arthritis or enteropathic arthritis disease spectrum, given the erosive, axial

nature of the arthritis in the *HLA-B27* pattern. This contrasts with the classically nonerosive, nonaxial nature of the arthritis in Behçet's disease. Oral aphthae, ocular lesions, erythema nodosum-like lesions, pustular vasculitis, and pyoderma gangrenosum all occur in patients with IBD.

Other Systemic Manifestations

Central nervous system (CNS) involvement is most commonly characterized by brain stem or corticospinal tract syndromes (neuro-Behçet's syndrome), venous sinus thrombosis, increased intracranial pressure secondary to venous sinus thrombosis or aseptic meningitis, isolated behavioral symptoms, or isolated headache.⁴⁷ Rarely, ruptured aneurysms, peripheral neuropathy, optic neuritis, and vestibular involvement can occur.⁴⁷ Poor prognosis is associated with a progressive course, parenchymal or brain stem involvement, cerebellar symptoms, and cerebrospinal fluid abnormalities.⁴⁸ Cranial and peripheral nerve involvement may also occur.

Patients with Behçet's disease may have gastrointestinal lesions resembling orogenital aphthae. These occur most commonly in the ileocecal region and in the ascending colon, transverse colon, or esophagus.³⁰ Large aphthae may lead to perforation. Presenting symptoms include abdominal pain, diarrhea, and melena. It is important to distinguish IBD from Behçet's disease.⁴⁹ Aphthae may also affect the bladder.

Pulmonary abnormalities are uncommon in Behçet's disease. Pulmonary artery aneurysms occur most frequently, followed by other complications secondary to vasculitis affecting the small pulmonary vessels. Aneurysm, thrombosis, hemorrhage, and infarction can result and cause death in patients with Behçet's disease.³¹

Renal manifestations are not common. They vary from minimal changes to proliferative glomerulonephritis and rapidly progressive crescentic glomerulonephritis. The pathogenesis likely involves immune complex deposition.⁵⁰

Cardiac complications include myocardial infarction, pericarditis, arterial and venous thromboses, and aneurysm formation. Thromboses more commonly involve the venous system, sometimes leading to superior and inferior vena cava obstruction.⁴⁰ Cardiac manifestations, either occlusive or aneurysmal, are postulated to occur due to a vasculitis of the vasa vasorum, which induces a thickening of the media and splitting of elastic fibers.⁵¹ Atherosclerosis does not appear to occur at an increased rate, as is seen in many autoimmune diseases such as systemic lupus erythematosus.⁵² Mortality in Behçet's disease is low and is usually related to pulmonary or CNS involvement or to bowel perforation.⁹

Limited data are available evaluating Behçet's in pregnancy. One case-control study reported more remissions than exacerbations during and after pregnancy with higher rates of pregnancy complications but no changes in neonatal outcomes.⁵³

HISTOPATHOLOGY

Histopathologic analysis of specimens from the cutaneous lesions seen in Behçet's disease reveals a neutrophilic

vascular reaction or even fully developed leukocytoclastic vasculitis. Microscopic examination of dermal capillary or venule walls shows neutrophilic infiltrates, nuclear dust, and extravasation of erythrocytes, with or without fibrinoid necrosis.⁵⁴ Immune complex-mediated vasculitis is the likely mechanism in the development of Behçet's disease.⁵⁵ A previously reported finding of lymphocytic vasculitis in patients with Behçet's disease is thought to represent an older lesion.⁴⁰

Biopsy specimens of synovial membranes reveal a neutrophilic reaction, with occasional plasma cells and lymphocytes. Immunofluorescence microscopy may show immunoglobulin G (IgG) deposition along the synovial membrane.⁴² Reports of synovial fluid analysis in patients with Behçet's disease show leukocyte counts ranging from 300 to 36,200 cells/mm³, with a predominance of neutrophils and normal glucose levels.⁵⁶ Synovitis is included as one of the O'Duffy-Goldstein criteria for the diagnosis of Behçet's disease.⁵⁷

DIAGNOSIS

The diagnosis of Behçet's disease can be difficult, particularly in patients with only a limited number of common features of the disease. Clinicians and investigators must rely on clinical criteria because there are no pathognomonic laboratory findings. Several sets of diagnostic criteria have been proposed including those by O'Duffy and Goldstein,⁵⁷ Mason and Barnes,⁵⁸ and a Japanese study group.⁵⁹ In 2008 the International Team for the Revision of International Criteria for Behçet's Disease revised the established criteria on the basis of the presence of various disease manifestations including oral aphthae, cutaneous lesions, positive

Table 93-1 Revised International Criteria for Behçet's Disease*

Oral aphthosis	1 point
Skin manifestations (pseudofolliculitis, skin aphthosis)	1 point
Vascular lesions (phlebitis, large vein thrombosis, aneurysm, arterial thrombosis)	1 point
Positive pathergy test	1 point
Genital aphthosis	2 points
Ocular lesions	2 points

*Diagnosis of Adamantiades-Behçet's disease is made with a score of 3 points.

Modified from International Team for the Revision of International Criteria for Behçet's Disease: Clinical manifestations of Behçet's disease. The ITR-ICBD report, *Clin Exp Rheumatol* 26(Suppl 50): S1–18, 2008.

pathergy, genital aphthae, and ocular involvement.⁶⁰ Each manifestation contributes 1 or 2 points with a diagnosis confirmed in an individual with a score of 3 or more points (Table 93-1). A diagnostic algorithm based on the Revised International Criteria for Behçet's disease is presented in Figure 93-3.

Although not required by diagnostic criteria, IBD, systemic lupus erythematosus, reactive arthritis, and herpetic infections should first be excluded because the presenting manifestations of these conditions are often similar to those of Behçet's disease. Recurrent aphthous stomatitis and complex aphthosis, defined as recurrent oral and genital aphthae or almost constant, multiple (three or more) oral aphthae, should also be considered in the differential diagnosis of patients presenting with oral or genital aphthae.⁶¹

The O'Duffy-Goldstein criteria mandate the presence of recurrent oral aphthae plus at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous

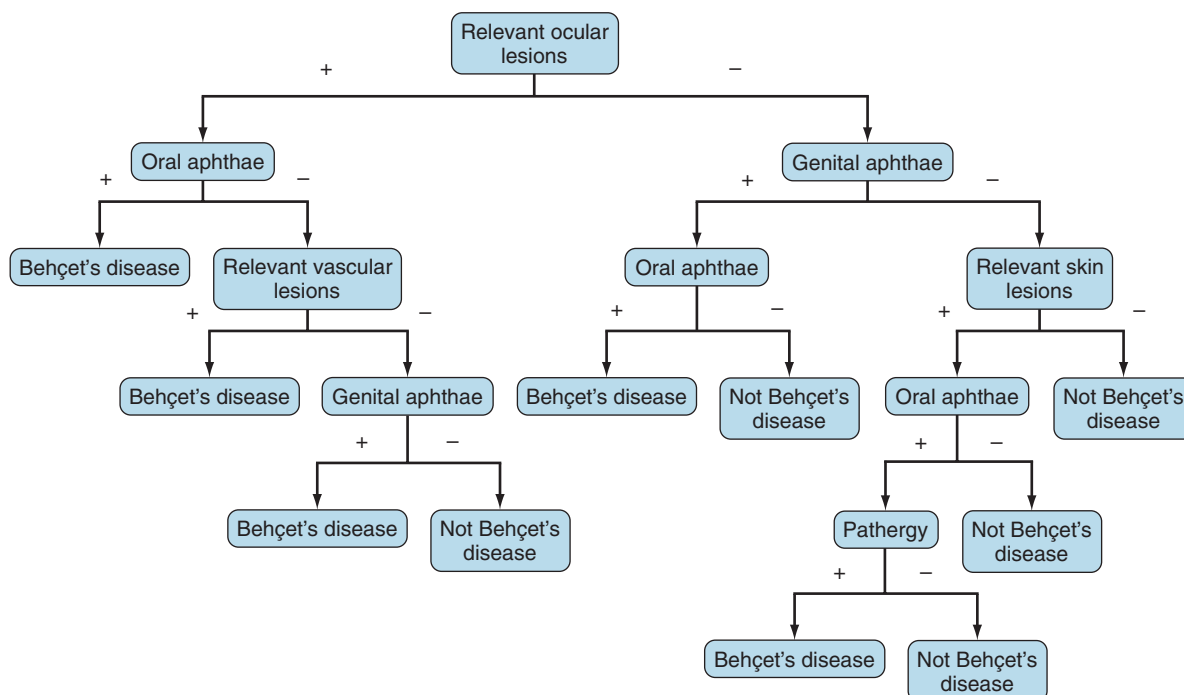

Figure 93-3 Revised international criteria for Behçet's disease: diagnosis of Adamantiades-Behçet's disease—classification tree format. (Modified from International Team for the Revision of International Criteria for Behçet's Disease: Clinical manifestations of Behçet's disease. The ITR-ICBD report, *Clin Exp Rheumatol* 26(Suppl 50):S1–18, 2008.)

pustular vasculitis, and meningoencephalitis. Patients who have only two of these findings, one being recurrent oral aphthae, are considered to have an incomplete form of Behçet's disease. Another concern with regard to the International Criteria for Behçet's is the inclusion of acneiform lesions, which are a common nonspecific finding in both adolescents and adults. Therefore our group advocates histologic confirmation of vessel-based histology to exclude acne lesions and the use of both the O'Duffy and the International Study Group criteria to exclude patients with IBD and enteropathic arthritis.⁶²

The initial evaluation should include referral for ophthalmologic consultation to identify insidious ocular involvement. Patients who have arthralgias, gastrointestinal symptoms, or neurologic abnormalities may require radiographic studies and evaluation by appropriate subspecialists. Cutaneous pustular lesions, erythema nodosum-like lesions, and pyoderma gangrenosum-like lesions should be biopsied (for both histologic evaluation and culture) to confirm the clinical diagnosis.

TREATMENT

Therapeutic options should be based on the degree of disease involvement (Tables 93-2 and 93-3).³⁸

Mucocutaneous Disease

Patients with oral and genital aphthae can be treated with intralesional, superpotent topical, or aerosolized (not inhaled) corticosteroids. Topical tacrolimus can also be used, often in combination with superpotent topical corticosteroids. Other palliative therapies include oral

Table 93-2 Treatment of Behçet's Disease

Mucocutaneous Disease Only
Topical, intralesional, or aerosolized corticosteroids
Topical sucralfate
Local anesthetics
Topical tacrolimus
Colchicine (1-2 mg/day)
Dapsone (50-150 mg/day)
Combinations of these agents
Severe Mucocutaneous Disease
Thalidomide (50-150 mg/day)
Methotrexate (2.5-25 mg/wk)
Prednisone
Interferon- α (3 million–9 million U/wk)
Systemic Disease
Prednisone
Azathioprine (50-200 mg twice daily)
Chlorambucil (4-6 mg/day)
Cyclophosphamide
Cyclosporine
Mycophenolate mofetil (1-1.5 g twice daily)
Intravenous immunoglobulin
Rituximab (severe ocular disease) ⁷⁵
Anti-tumor necrosis factor agents

tetracycline solutions, topical anesthetics, and rinses containing chlorhexidine gluconate. Oral colchicine, 1 to 2 mg daily, can decrease the size and frequency of mucocutaneous lesions.^{63,64} Doses can be adjusted according to the degree of gastrointestinal upset experienced by the patient. Dapsone in a dose of 50 to 150 mg/day is often helpful alone⁶⁵ or in combination with colchicine.⁶¹ Patients must be monitored for the development of hemolytic anemia and

Table 93-3 Modified EULAR 2008 Recommendations for the Management of Behçet's Disease (BD)

No.	Recommendation
1	Any patient with BD and inflammatory eye disease affecting the posterior segment should be on a treatment regimen that includes azathioprine, or equivalent mycophenolate,* and systemic corticosteroids.
2	If the patient has severe eye disease defined as >2 lines of drop in visual acuity on a 10/10 scale and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either cyclosporine A or infliximab be used in combination with azathioprine and corticosteroids; alternatively, IFN- α with or without corticosteroids could be used instead. <i>Rituximab is also an effective treatment for severe eye disease.</i> ⁷⁵
3	There is no firm evidence to guide the management of major vessel disease in BD. For the management of acute deep vein thrombosis in BD immunosuppressive agents such as corticosteroids, azathioprine, cyclophosphamide, or cyclosporine A are recommended. For the management of pulmonary and peripheral arterial aneurysms, cyclophosphamide and corticosteroids are recommended.
4	Similarly, there are no controlled data on, or evidence of benefit from, uncontrolled experience with anticoagulants, antiplatelet, or antifibrinolytic agents in the management of deep vein thrombosis or for the use of anticoagulation for the arterial lesions of BD.
5	There is no evidence-based treatment that can be recommended for the management of gastrointestinal involvement of BD. Agents such as sulfasalazine, corticosteroids, azathioprine, TNF antagonists, and thalidomide should be tried first before surgery, except in emergencies.
6	In most patients with BD, arthritis can be managed with colchicine.
7	There are no controlled data to guide the management of CNS involvement in BD. For parenchymal involvement, agents to be tried may include corticosteroids, IFN- α , azathioprine, cyclophosphamide, methotrexate, and TNF antagonists. For dural sinus thrombosis corticosteroids are recommended.
8	Cyclosporine A should not be used in BD patients with CNS involvement unless necessary for intraocular inflammation.
9	The decision to treat skin and mucosa involvement will depend on the perceived severity by the doctor and the patient. Mucocutaneous involvement should be treated according to the dominant or codominant lesions present. Topical measures (i.e., local corticosteroids) should be the first line of treatment for isolated oral and genital ulcers. Colchicine should be preferred when the dominant lesion is erythema nodosum. <i>Dapsone may also be used.</i> Leg ulcers in BD might have different causes. Treatment should be planned accordingly. <i>Thalidomide, azathioprine, IFN-α, and TNF antagonists may be considered in resistant cases.</i>

*Our modifications to the recommendations are noted in italics.

CNS, central nervous system; EULAR, European League Against Rheumatism; IFN- α , interferon-alpha; TNF, tumor necrosis factor.

From Hatemi, G, Silman, A, Bang, D, et al: EULAR recommendations for the management of Behçet disease, *Ann Rheum Dis* 67:1656, 2008.

methemoglobinemia; the glucose-6-phosphate dehydrogenase level should be checked in all patients before beginning therapy with dapsone. Etanercept has also been shown to improve mucosal and skin manifestations of Behçet's disease.⁶⁶

Severe Mucocutaneous Disease

Patients who fail to respond to conservative therapy as outlined for mucocutaneous disease may require thalidomide. Its mechanism of action is thought to be mediated by modulation of TNF and other cytokines. Previous studies have shown that thalidomide is an effective agent for the treatment of severe mucocutaneous lesions of Behçet's disease.^{67,68} Thalidomide is known to cause severe birth defects, and all patients and prescribing physicians must adhere to the System for Thalidomide Education and Prescribing Safety (STEPS) protocol including monthly follow-up visits.⁶⁹ Patients receiving thalidomide can be monitored with nerve conduction studies for the development of peripheral neuropathy, if doing so is warranted on the basis of the clinical neurologic evaluation. Of note, the cost of treatment increased drastically when thalidomide was approved for the treatment of multiple myeloma.

Low-dose oral methotrexate (2.5 to 25 mg/wk) and low-dose prednisone are alternatives for patients with severe mucocutaneous involvement.^{64,70} Patients receiving methotrexate should be monitored for the development of hepatotoxicity and leukopenia. The risk of rebound after the tapering or discontinuation of systemic prednisone greatly limits its use for mucocutaneous disease alone. In addition, interferon- α is effective for severe mucocutaneous lesions and some systemic manifestations.^{71,72} A review of the safety and efficacy of interferon- α by Zouboulis and Orfanos⁷¹ recommended a 3-month high-dose regimen of 9 million units three times per week, followed by a low, maintenance dose of 3 million units three times per week. Patients do experience the usual flulike symptoms associated with this therapy.

Systemic Disease

Patients with systemic disease such as ocular and cardiovascular abnormalities require immunosuppressive therapy, particularly in view of the risk of morbidity and mortality resulting from untreated disease. Systemic corticosteroids may be used alone or in combination with other immunosuppressive agents such as azathioprine, interferon- α , cyclosporine, cyclophosphamide, and chlorambucil.^{64,73} The standard of care for eye disease is prednisone plus azathioprine.⁷⁴ If this combination is not successful, one of the aforementioned immunosuppressive agents or mycophenolate mofetil can be substituted for azathioprine.⁷³ Rituximab has also been effective in the treatment of severe ocular manifestations of Behçet's disease.⁷⁵ Several of these immunosuppressive agents have associated hematologic toxicity, as well as the potential for the development of associated malignancies; therefore close monitoring is essential. There have also been reports of Behçet's disease treated with anti-TNF agents. A double-blind, placebo-controlled trial showed that etanercept was successful in suppressing most of the mucocutaneous manifestations of Behçet's disease.⁷⁶

Other reports support the efficacy of adalimumab and infliximab.^{77,78} In 2008 the European League Against Rheumatism (EULAR) developed a standard of recommendations for the management of the various systemic manifestations of Behçet's disease (see Table 93-3).

OUTCOME

Behçet's disease has a variable clinical course in most patients with a pattern of exacerbations and remissions. A delay in diagnosis after the initial manifestation of Behçet's disease is common. Most patients present initially with mucocutaneous manifestations, and evidence of ocular and neurologic involvement may appear several years after diagnosis. Patients with the finding of complex aphthosis may represent a forme fruste of Behçet's disease, and they should be monitored for the development of additional abnormalities fulfilling the diagnostic criteria through regular follow-up and referral to appropriate specialists.⁶¹ The greatest morbidity is associated with ocular manifestations (two-thirds of patients), vascular disease (one-third of patients), and CNS disease (10% to 20% of patients).⁷⁹ The most common cause of morbidity is ocular involvement; manifestations such as posterior uveitis and retinal vasculitis can cause blindness. Mortality in Behçet's disease is low and is usually related to pulmonary or CNS involvement or to bowel perforation.⁹

Etiology and Pathogenesis of Hyperuricemia and Gout

ROBERT T. KEENAN • JOHANNES NOWATZKY •
MICHAEL H. PILLINGER

KEY POINTS

Uric acid is the biologically active end product of human purine metabolism.

Serum urate concentrations are determined by the balance between urate production and elimination; hyperuricemia results from urate overproduction, urate underexcretion, or a combination of both.

Specific organic anion transporters (OATs) have recently been identified as playing a central role in the excretion of urate by the kidney.

Hyperuricemia is defined as serum urate levels greater than 6.8 mg/dL, the limit of its solubility in serum.

Gout pathogenesis requires the accumulation of monosodium urate at levels sufficient to drive the precipitation of crystals, resulting in the initiation of an inflammatory response.

Monosodium urate crystals activate the NLRP3 (NALP3) inflammasome, a multimolecular cytosolic complex that processes and generates interleukin-1 β (IL-1 β), IL-18, and IL-33.

The initiation of gouty inflammation by local white blood cells induces an influx of neutrophils into the joint; when these neutrophils encounter urate crystals, they become activated and propagate further inflammation.

Low-level inflammation is present in chronic gout and tophaceous gout; macrophages continue to produce cytokines and proteases, thereby facilitating cartilage and bone destruction.

The ancient disease gout has a complex pathogenesis, and its modern relevance is underscored by a rise in prevalence by as much as fourfold in the past half century. Indeed, gout is now the most common inflammatory arthritis in the United States.¹ Gout is a disease of both metabolism and inflammation/immunity. Gout pathogenesis requires the intersection of two distinct processes: (1) the intrinsic formation of uric acid, in the form of urate, at levels sufficient to drive the precipitation of urate into crystallized forms and

(2) an inflammatory response to the crystals so formed. How these processes occur and under what circumstances they cross from adaptive to pathologic responses are the subjects of this chapter.

EVOLUTIONARY CONSIDERATIONS

KEY POINT

High baseline levels of serum urate in humans may be the result of evolutionary pressures in an era when hyperuricemia provided survival benefits.

The metabolic production of uric acid is ubiquitous among mammals and many other forms of animal life, and it is important to recognize that urate generation is not a priori pathologic. Indeed, the production of uric acid may serve one, or possibly a multitude of beneficial roles, an area of interest to molecular immunologists and molecular anthropologists alike.

Uric Acid as a Danger Signal

Uric acid is a breakdown product of purine metabolism. As such, it represents a metabolic waste molecule that might, in theory, be nothing more than a nuisance requiring excretion. However, studies by Shi and colleagues² and others suggest that evolution has co-opted this waste-generating process to play an important and perhaps critical role in organismal immunity. It had long been appreciated that the lysates of damaged mammalian cells can serve effectively as adjuvants—that is, can promote immune responses to injected antigens. Recently Shi and colleagues² used classical biochemical techniques to demonstrate that the major endogenous adjuvant found in damaged cells was uric acid. These investigators further demonstrated that uric acid had the capacity to promote T cell activation in response to

antigen and that aggressive urate-lowering treatment could abrogate murine immune responses. Thus uric acid may serve as a *danger signal* to promote immune responses. As first proposed by Matzinger, a *danger signal* is an intrinsically produced molecule, typically issued by an altered or damaged cell in order to alert the immune system to the need for an immunologic response.³ Viewed from this perspective, the production of uric acid in a virally infected cell, for example, might serve as an upstream “second signal” to promote antigen presentation by a professional antigen-presenting cells such as dendritic cells, macrophages, or B cells. Indeed, although damaged or dying cells tend to have limited ability to manufacture proteins, their output of uric acid characteristically increases during cellular breakdown. The uric acid danger signal might also play an important role in tumor immunity, and at least one mouse model suggests that modulation of uric acid levels may directly affect immune tumor rejection.⁴ Although these observations require more study, they are consistent with a paradigm in which urate production at the local cellular level may play an important role in immunity and homeostasis.

Uric Acid and Human Evolution

Most mammals have serum urate levels in a range roughly between 0.5 and 2 mg/dL. In contrast, humans and other primates, including some New World monkeys, typically demonstrate serum urate levels between 4 and 6 mg/dL. The genetic and biochemical basis for these increases is well appreciated. During the Miocene era (10 to 25 million years ago), mutations in various primate and some monkey species resulted in inactivation of the uricase gene, which codes for the enzyme that degrades uric acid to allantoinic acid. Genetic studies indicate that the uricase gene experienced nonsense mutations during that period, not once but multiple times across multiple hominoid lineages (Figure 94-1).^{5,6} The occurrence of multiple independent loss-of-function mutations has led some biologists to hypothesize that increases

in urate generation may have conferred a survival benefit for these particular species. Several compelling, and not necessarily mutually exclusive, hypotheses have been proposed.

Ames and colleagues⁷ noted the fact that these same primate species had also been subject to a unique deletion of the gene permitting organisms to produce ascorbic acid, an event that apparently occurred in the Eocene era, some 10 to 20 million years before the uricase deletions. In mammals that do produce ascorbic acid, this molecule serves as the pre-eminent antioxidant in the body. Thus the loss of ascorbate production may have been an evolutionary liability, for which increases in urate provided compensation, particularly as a protectant against aging and cancer.⁷ Other authors have suggested that the effects of urate may have been particularly important in the central nervous system and that hyperuricemia provided an evolutionary advantage by promoting hominoid intellectual function, either through its antioxidant effects or via activation of neurostimulatory adenosine receptors (in a manner similar to that of caffeine).⁸ Although the antioxidant theory would appear compelling, critics have pointed out that (1) the production of urate itself generates oxidant molecules, diminishing any possible urate benefit; (2) intracellular urate may have pro-oxidant effects⁹; and (3) the human/primate capacity for antioxidation may be large even in the absence of soluble antioxidants; for example, human red cell membranes have extensive antioxidant capacities.¹⁰

Other investigators have examined the specific evolutionary pressures exerted on primate species during the Miocene era, in an attempt to understand the potential advantages of urate elevations. Johnson and colleagues¹² pointed out that the Miocene era was an important era in hominoid evolution and that the hominoid diet during that time appears to have been mainly vegetarian and extremely low in salt. They suggest that hominoids during that period may have experienced a “hypotensive crisis,” particularly in the face of the transition to upright walking. They further postulate that an elevation in serum uric acid levels provided a mechanism for restoring normotension, primarily through urate-induced renovascular injury.^{11,12} To model this hypothesis, these investigators exposed rats to a low-salt diet, resulting in hypotension. When treated with the uricase inhibitor oxonic acid (to mimic the primate uricase loss), the rats’ urate levels rose and their blood pressures normalized. The effects of uricase inhibition on blood pressure could be reversed through the use of the urate-lowering agent allopurinol. These observations imply that what may once have been a homeostatic adaptation could now contribute to essential hypertension in today’s salt-rich era. In support of the latter hypothesis, Feig and colleagues¹³ identified adolescents with premature essential hypertension and hyperuricemia and treated them with the urate-lowering agent allopurinol. The result was normalization in blood pressure that reversed after allopurinol discontinuation.

Although the loss of uricase promoted serum urate increases in humans and other hominoids, the levels of serum urate so achieved were not sufficient to promote urate crystallization and gout. Rather, uricase inactivation created the circumstances under which additional increases in urate

Figure 94-1 Mutations affecting the uricase gene. During the Miocene era, hominoid species experienced not one but multiple different mutations, resulting in the loss of uricase activity. The survival of multiple species harboring different mutations suggests that loss of uricase may have conveyed a survival advantage, even as it established the necessary precondition for hyperuricemia and gout. (Modified with permission from Wu XW, Muzny DM, Lee CC, Caskey CT: Two independent mutational events in the loss of urate oxidase during hominoid evolution, *J Mol Evol* 34:78–84, 1992. © Springer-Verlag GmbH.)

production, or impairments in urate excretion, can result in serum urate concentrations exceeding the solubility threshold. Accordingly, we next review the mechanisms of urate production and excretion, as well as the events that may tip the scales toward pathologic hyperuricemia.

URIC ACID PRODUCTION AND EXCRETION: NORMAL LEVELS AND HYPERURICEMIA

Uric acid is a breakdown product of purines, and uric acid generation therefore depends directly on both intrinsic purine production and purine intake. In humans, uric acid is an end-product metabolite; consequently the depletion of uric acid depends directly on its excretion. The balance between uric acid production and excretion determines the serum urate level. Most individuals maintain a relatively stable uric acid level between 4 and 6.8 mg/dL and a total body uric acid pool of approximately 1000 mg.¹⁴ However, it is increasingly appreciated that individuals with high serum uric acid levels may deposit uric acid either occultly or in the form of appreciable masses (tophi), with the consequence that the total body urate pool may be significantly higher than in nonhyperuricemics.¹⁵ Such occult deposition of uric acid (total body urate burden) may have implications for treatment because they may form a “buffering reservoir” of urate that resists initial treatment with urate-lowering agents.

Urate Production: Purine Metabolism and Intake

KEY POINT

Uric acid is the end product of human purine metabolism.

In addition to the intrinsic synthesis and extrinsic intake of purines, uric acid production also depends on the metabolic processes that convert purines into uric acid. Next, we review purine and uric acid synthesis; purine intake is discussed later following Diet and Uric Acid.

Purine Biosynthesis

Purines are heterocyclic aromatic compounds, consisting of conjoined pyrimidine and imidazole rings (Figure 94-2). In mammals, the most common expression of purines is found in the form of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) (containing the purines adenine and guanine), as well as single-molecule nucleotides (adenosine triphosphate [ATP], adenosine diphosphate [ADP], adenosine monophosphate [AMP], cyclic AMP, and to a lesser extent, guanosine triphosphate [GTP] and cyclic guanosine monophosphate [GMP]). Purines are also critical elements of the energy metabolism molecules NADH, NADPH, and coenzyme Q. Purines may also serve as direct neurotransmitters; for example, adenosine may interact with receptors

Figure 94-2 Structure of uric acid and common purines. All purine bases may exist in the lactam form in a reversible manner as shown for uric acid.

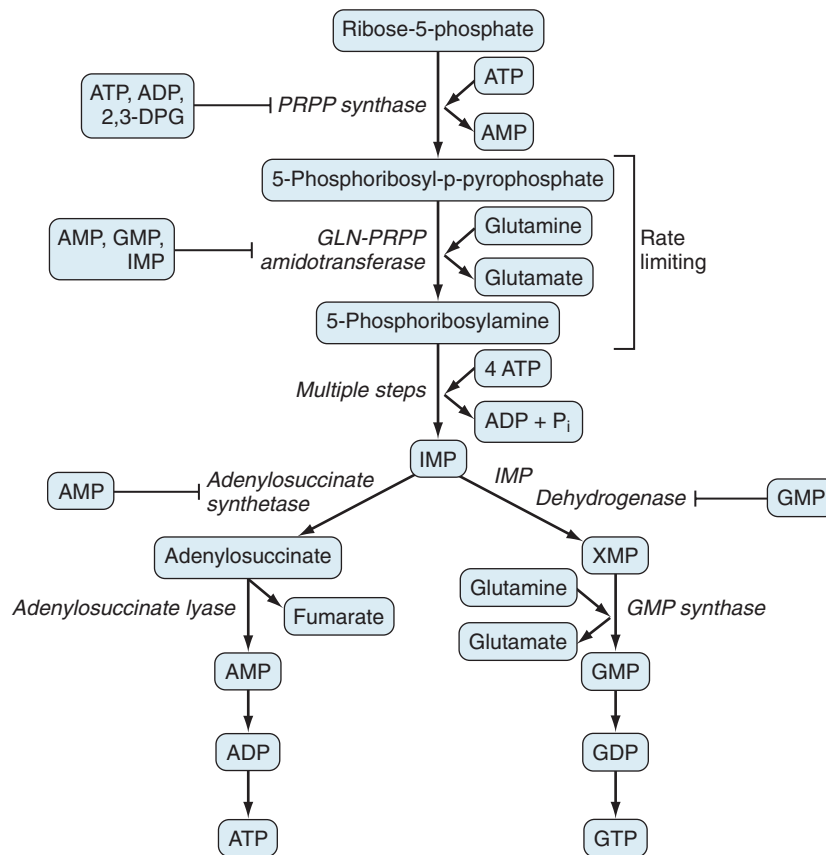

Figure 94-3 Purine biosynthesis. See text for details. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; 2,3-DPG, 2,3-diphosphoglycerate; GDP, guanosine diphosphate; GLN, glutamine; GMP, guanosine monophosphate; GTP, guanosine triphosphate; IMP, inosine monophosphate; PRPP, phosphoribosyl pyrophosphate; XMP, xanthine monophosphate.

to modulate cardiovascular and central nervous system function.¹⁶

Purine biosynthesis is initiated on a core of ribose-5-phosphate (Figures 94-3 and 94-4). The enzyme phosphoribosyl pyrophosphate (PRPP) synthase catalyzes the addition of a pyrophosphate moiety to form the adduct PRPP. This reaction is thought to be rate limiting. Subsequently, the enzyme glutamine-PRPP amidotransferase catalyzes the interaction of PRPP with glutamine to form 5-phosphoribosyl amine, the commitment step in purine biosynthesis. Glutamine-PRPP amidotransferase and PRPP synthase are both subject to feedback inhibition by IMP, AMP, and GMP, providing a mechanism to slow purine biosynthesis in the setting of purine sufficiency. 5-phosphoribosyl amine next forms the backbone for a series of molecular additions, ending in the formation of the

purine inosine monophosphate (IMP). IMP is converted into either adenosine monophosphate (AMP) or guanosine monophosphate (GMP), which can then be phosphorylated into higher-energy compounds. Collectively, the process of purine biosynthesis is highly energy dependent, requiring the consumption of multiple molecules of ATP. Thus purine biosynthesis not only directly increases the substrate load for urate generation but also increases the turnover of already-formed purines that contribute to increased urate levels.¹⁷

Urate Formation and Purine Salvage

Purines generated by the previously described mechanisms are susceptible to enzymatic catabolism, presumably to maintain purine homeostasis (Figure 94-5). Purines

Figure 94-4 Formation of phosphoribosyl pyrophosphate by phosphoribosyl pyrophosphate synthase. In some patients, this reaction proceeds too rapidly, promoting hyperuricemia on the basis of primary overproduction of uric acid.

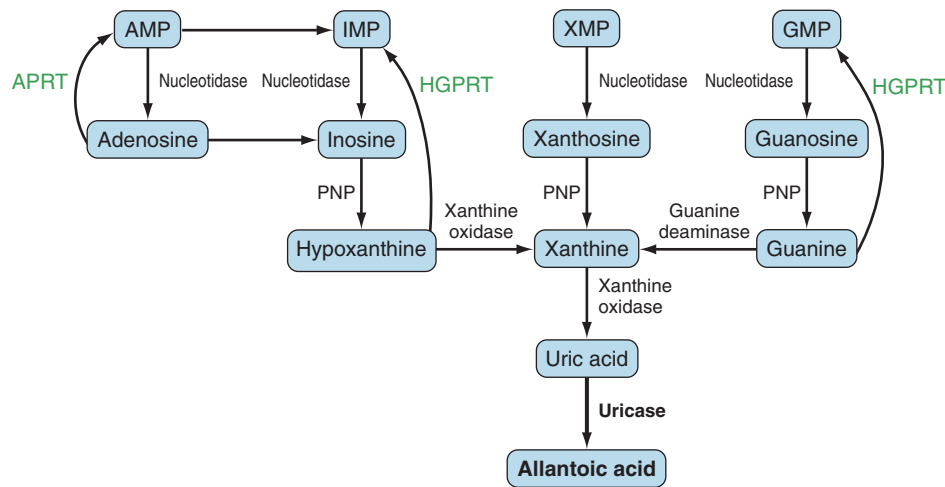

Figure 94-5 Uric acid synthesis and purine salvage. Catabolism of purines, especially inosine monophosphate (IMP) and guanosine monophosphate (GMP), results in urate synthesis via the common substrate xanthine. Xanthine oxidase is necessary for urate synthesis from any purine and so serves as a target for agents that inhibit uric acid synthesis (e.g., allopurinol, febuxostat). Purine salvage via hypoxanthine guanine phosphoribosyl transferase (HGPRT) returns hypoxanthine and guanine to IMP and GMP, respectively. HGPRT deficiencies result in not only increases in hypoxanthine and guanine and subsequent uric acid synthesis but also in the depletion of nucleotides that provide feedback inhibition on purine biosynthesis. Denoted in *bold*, mammals other than primates and some monkeys possess uricase, which converts uric acid to allantoic acid for further degradation. APRT, adenine phosphoribosyl transferase; AMP, adenosine monophosphate; PNP, purine nucleotide phosphorylase; XMP, xanthine monophosphate.

susceptible to degradation include the monophosphate nucleotides GMP and IMP. These molecules are converted by nucleotidases to their purine base forms, guanosine and inosine. In contrast to GMP and IMP, AMP is not susceptible to nucleotidase activity. However, AMP can undergo conversion, through the activity of adenylylase, into IMP for further degradation. Additionally, adenosine deaminase can convert adenosine to inosine for inclusion in the degradative pathway. Further catabolism of both guanosine and inosine is mediated by the common enzyme purine nucleoside phosphorylase (PNP). Guanosine is converted to guanine, whereas inosine is converted to hypoxanthine. Both guanine and hypoxanthine are subsequently converted to xanthine, by the enzymes guanine deaminase and xanthine oxidase (also known as *xanthine dehydrogenase*), respectively. Xanthine from either source is then converted directly to uric acid, again by the action of xanthine oxidase. As noted earlier, organisms other than humans and primates including New World monkeys possess an additional enzyme—uricase (urate oxidase), which converts uric acid to allantoic acid, a relatively soluble compound that can be further degraded to urea. Lacking this enzyme, human and primate purine metabolism ceases with the production of uric acid.¹⁸

Presumably because purine synthesis is energy expensive for the cell, evolution has dictated that mechanisms exist to recover purines before they completely traverse the degradative pathway. These pathways, collectively known as *purine salvage*, are intimately connected to the feedback regulation of purine synthesis. The major enzyme responsible for purine salvage, hypoxanthine/guanine phosphoribosyl transferase (HGPRT), catalyzes the transfer of a phosphoribose from PRPP to either hypoxanthine or guanine, to form inosinate or guanylate, respectively (Figure 94-6). These products are then available for reinclusion in the available purine pool. A second salvage enzyme is adenine phosphoribosyl transferase (APRT), which restores

adenine to adenylate. However, as described earlier, most adenosine/adenine breakdown occurs via conversion to inosinic acid. The failure of APRT deficiencies to alter uric acid production suggests that APRT plays only a minor or redundant role in purine salvage.¹⁹

Urate Overproduction: Primary and Secondary Causes

KEY POINT

Hyperuricemia may result from urate overproduction owing to primary or secondary causes.

Primary Urate Overproduction

In some patients, inborn errors of metabolism lead to urate overproduction and subsequent hyperuricemia. Several of these deserve mention. First, a small number of individuals possess PRPP synthase enzymes that are hyperactive. The result is increased generation of PRPP. Because under normal circumstances PRPP concentrations are below the K_m of glutamine-PRPP amidotransferase for this substrate, increased PRPP levels drive amidotransferase activity and accelerate purine biosynthesis.

The second well-described class of abnormality occurs within the purine salvage pathway. Deficiencies of HGPRT result in impaired purine salvage and increased substrate for uric acid generation. Additionally, because purine salvage normally results in nucleotide monophosphate generation, patients with purine salvage failure experience lower levels of nucleotide monophosphates, as well as loss of feedback inhibition of both PRPP synthase and glutamine-PRPP amidotransferase. As a result, purine salvage failure resulting from HGPRT deficiency is accompanied by purine overproduction.

Figure 94-6 Action of hypoxanthine guanine phosphoribosyl transferase (HGPRT). Loss of HGPRT activity results in hyperuricemia and, in severe cases, the neurologic deficits of Lesch-Nyhan syndrome.

Two major variants of HGPRT deficiency have been described. Complete HGPRT deficiency, better known as *Lesch-Nyhan syndrome*, is an X-linked recessive disorder characterized by extremely high levels of serum urate, gouty attacks, nephrolithiasis, mental retardation, movement, and behavioral disorders including self-mutilating behavior. The disorder can occasionally arise by de novo mutation; female carriers are generally asymptomatic but may have elevated serum urate levels. In contrast to the gouty attacks and nephrolithiasis, which are direct consequences of hyperuricemia, the neurologic findings in Lesch-Nyhan syndrome are independent of hyperuricemia and unresponsive to urate-lowering drugs. Life expectancy can be greatly reduced, and these patients rarely come to the attention of adult rheumatologists.²⁰

In contrast to Lesch-Nyhan patients, individuals with Kelley-Seegmiller syndrome have a partial deficiency of HGPRT.²¹ Kelley-Seegmiller patients typically present with hyperuricemia and gout and have limited or no neurologic symptoms.²² Several variants of Kelley-Seegmiller syndrome have been described, based on the extent of HGPRT inactivity and the presence/absence of neurologic findings. The mutations seen in the Kelley-Seegmiller variants tend to occur in regions of the *HGPRT* gene other than those identified in Lesch-Nyhan patients (whose mutations typically localize to the PRPP-binding region); whether such differences influence the presence/absence of neurologic symptoms has not been determined.²³

Several hereditary defects of energy metabolism also promote hyperuricemia, mainly as a consequence of ATP consumption. Patients with glucose-6-phosphatase deficiency (type I glycogen storage, or von Gierke's disease) demonstrate a high rate of both purine and ATP turnover. The lactic acidemia that secondarily occurs in patients with glucose-6-phosphatase deficiency may also contribute to hyperuricemia, by promoting decreased renal urate excretion (see later).²⁴ In fructose-1-phosphate aldolase deficiency, patients lack the capacity to metabolize

fructose-1-phosphate. Fructose-1-phosphate accumulation causes feedback inhibition of fructokinase and fructose accumulation in the blood. As an apparent consequence of these changes, AMP accumulates and promotes hyperuricemia by the mechanisms described earlier.²⁵ The role of fructose intake in patients without inborn errors of fructose metabolism is discussed further later.

Secondary Urate Overproduction and Hyperuricemia

A number of secondary causes can lead to urate overproduction and hyperuricemia. In most cases, these conditions induce increased cell turnover, with resultant purine generation and breakdown. Chief among these must be counted diseases of erythropoietic, lymphopoietic, and myelopoietic cell turnover, of both malignant and nonmalignant varieties. Among the erythropoietic diseases causing hyperuricemia, autoimmune, and other hemolytic anemias (red cell destruction with increased red cell generation), sickle cell disease,^{26,27} polycythemia vera,²⁸ and ineffective erythropoiesis (e.g., in pernicious and other forms of megaloblastic anemia, thalassemia, and other hemoglobinopathies) must be included.²⁹ Patients with myeloproliferative and lymphoproliferative disorders including myelodysplastic syndrome, myeloid metaplasia, leukemias, lymphomas, and paraneoplastic diseases such as multiple myeloma and Waldenström's macroglobulinemia are also at increased risk for hyperuricemia.^{30,31} In some cases, particularly in the pediatric setting, hyperuricemia and concomitant renal failure may be the first presentation of these malignancies.³² Indeed, the level of hyperuricemia may correlate with the degree of disease and cell turnover. Patients with essential thrombocytosis may also be at increased risk for hyperuricemia.³³ An association between solid tumors and hyperuricemia has been reported³⁴; given the slower turnover of solid tumor cells, solid tumor hyperuricemia tends to be less

common and less severe than that seen in malignancies of bone marrow–derived cells.

Tumor lysis syndrome represents a unique form of tumor-related hyperuricemia, in which cell death induced by chemotherapy results in not only hyperuricemia but also hyperphosphatemia, hyperkalemia, and hypocalcemia, often resulting in acute renal failure and arrhythmias. Although tumor lysis syndrome occurs most commonly during treatment for hematologic malignancies, it may also occur during treatment of solid tumors.³⁵ Although not well documented in the literature, the authors have noted hyperuricemia subsequent to the use of granulocyte colony-stimulating factor for myelofibrosis-associated anemia. Such use of colony-stimulating factors may secondarily contribute to the new onset of gout.³⁶

Although somewhat more controversial, the increased cell turnover in patients with psoriasis has also been associated with elevated levels of serum urate.^{37,38} An association between sarcoidosis and hyperuricemia has also been proposed,³¹ again presumably relating to increased cell turnover and/or metabolic activity. However, the epidemiologic evidence supporting sarcoidosis as a cause of hyperuricemia is less than convincing.³⁹

Conditions leading directly to the physiologic consumption/degradation of ATP also contribute to the potential for secondary purine turnover leading to hyperuricemia. Thus strenuous and prolonged exercise, particularly to levels driving anaerobic respiration, may induce transient serum urate elevations.^{40,41} *Status epilepticus* is likely to mimic these events. A number of acute illnesses including myocardial infarction and sepsis are also accompanied by ATP catabolism and may result in transient hyperuricemia.³⁴ Patients with hereditary myopathies including metabolic myopathies such as glycogen storage disease types III, V, and VII (debranching enzyme deficiency, myophosphorylase deficiency, and muscle phosphofructokinase deficiency, respectively), as well as mitochondrial myopathies (including carnitine palmitoyltransferase deficiency and myoadenylate deaminase deficiency), are susceptible to increases in serum urate levels after even moderate exercise.^{34,42,43} In these individuals, a limited ability to synthesize ATP on demand apparently results in a rapid turnover of established ATP pools during exercise, with resultant purine and uric acid formation. Patients with medium-chain acyl-coenzyme A dehydrogenase deficiency, a defect of fatty acid metabolism, have also been shown to have elevated levels of serum urate, although the mechanism for this effect is not entirely clear.⁴⁴

Urate Excretion: Gastrointestinal and Renal Mechanisms

KEY POINT

Urate excretion occurs via the gut and the kidneys. In the kidneys, a complex series of urate transport proteins mediates a net elimination of sodium urate.

In most patients, serum urate level is maintained within a narrow range. Accordingly, mechanisms must exist to ensure disposal of urate, either by metabolism or excretion. As

noted earlier, humans possess little or no capacity to metabolize urate; therefore urate excretory mechanisms play a critical role in homeostasis. The gastrointestinal tract and the kidneys each participate in urate excretion.

Gastrointestinal Excretion of Urate

Uric acid elimination via the gastrointestinal tract has been recognized for more than 50 years but has been relatively little studied. On the basis of radiolabeled urate tracer studies, Sorensen estimated that in healthy individuals, the gastrointestinal tract is responsible for the excretion of 20% to 30% of the daily uric acid burden.⁴⁵⁻⁴⁷ Thus gastrointestinal excretion of uric acid may represent a minor pathway for urate excretion under most circumstances. Gastrointestinal uric acid excretion may become more important in settings of renal insufficiency, however, particularly in view of animal studies suggesting that uric acid excretion via the gut may increase in a compensatory manner in the setting of renal failure and decreased renal uric acid excretion.⁴⁸ Mechanisms of uric acid transport into the gut appear to include exocrine secretion (saliva, gastric, and pancreatic juices), as well as direct bowel secretory mechanisms.³⁴ Uric acid is apparently excreted into the gut in its native form and then undergoes degradation by intestinal flora.⁴⁷

Renal Excretion of Uric Acid: Normal Mechanisms

In all but the most extreme circumstances of renal failure, the kidney comprises the primary organ for uric acid excretion. The mechanisms of renal urate excretion are complex and involve multiple steps. In the bloodstream, uric acid (in the form of urate anion) is considered to be completely or nearly completely unbound to plasma proteins. As a result, nearly 100% of the urate load entering the renal afferent arteriole undergoes ultrafiltration by the glomerulus. As discussed further later, decreases in glomerular function therefore reduce urate filtration and promote rises in serum urate levels.

Subsequent to ultrafiltration, urate (initially in a monovalent ion form) undergoes several distinct handling steps: (1) a *resorption step*, in which as much as 90% to 98% of the filtered urate undergoes reclamation; (2) a *secretion step*, in which most of the urate resorbed in step 1 is retransferred back into the tubule lumen; and (3) a possible additional *resorption step* in which a smaller amount of uric acid is then resorbed. The net result is excretion of approximately 10% of the filtered load. In fully functioning nephrons, these steps are responsive to serum urate levels, such that rises in serum urate induce increased renal excretion and maintenance of total body urate homeostasis. Early studies, particularly in mouse models, suggested that these three steps might occur in anatomic sequence, in the proximal tubule, descending loop of Henle, and distal convoluted tubule, respectively. However, studies in humans over the past decade including both genetic and physiologic approaches suggest that these functions are likely to overlap and to occur mainly in the proximal tubule. Moreover, these same studies have emphasized the importance of organic anion transporters (OATs) and other active and passive transport molecules in the movements of urate in both directions across the proximal tubule (Figure 94-7).^{49,50}

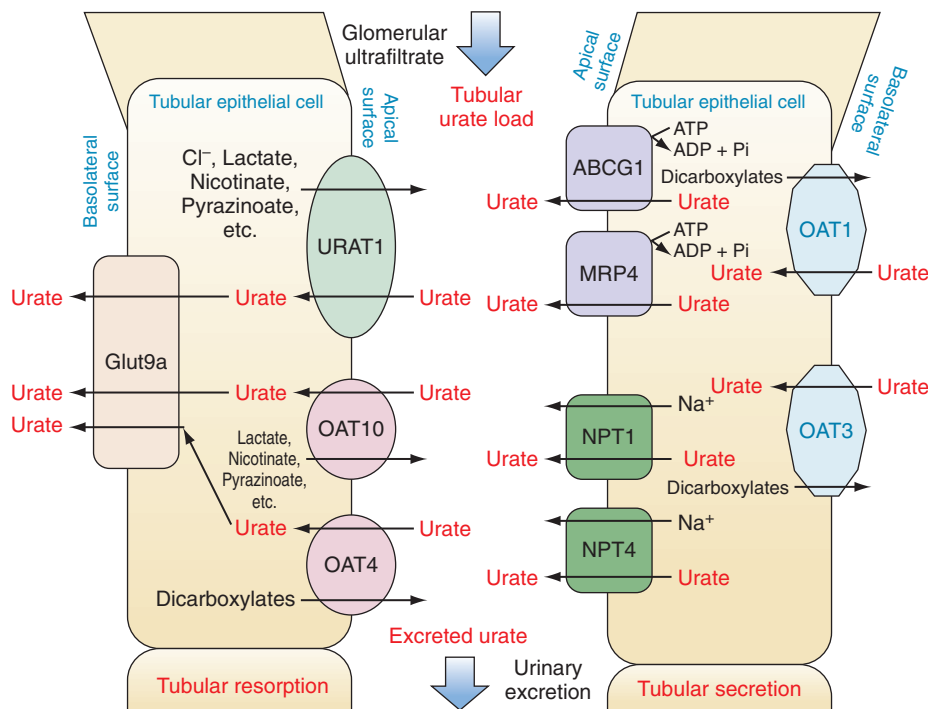

Figure 94-7 Renal tubular handling of urate. Both urate resorption and urate secretion are handled by the epithelial cells of the proximal tubule. For simplicity, resorption is shown on the left and secretion on the right of the figure. **Resorption:** multiple apical transporters (URAT1, OAT4, OAT10) move urate from the proximal tubule ultrafiltrate into the epithelial cytosol. Of these, URAT1 appears to be most important. Both inorganic (Cl^-) and organic (e.g., lactate, nicotinate, pyrazinoate) counter-ions promote urate transport at this step; therefore rises in organic acid levels can promote urate retention and hyperuricemia. Urate is subsequently transported from the cell to the interstitium by the basolateral transporter Glut9a. **Secretion:** The organic anion transporters OAT1 and OAT3 move urate from the interstitium to the epithelial cell interior, using dicarboxylates as counter-ions. Urate within the epithelial cell is moved out to the tubular fluid by multiple transporters. Urate secretion by some transporters (ABCG1, MRP4) is adenosine triphosphate (ATP) dependent, whereas other transporters (NPT1, 4) move urate via cotransport of Na^+ . Accordingly, sodium depletion can promote hyperuricemia. ADP, adenosine diphosphate.

Urate Resorption. Urate resorption in the proximal tubule depends on the action of several apical surface transporters and at least one resorption transporter at the basolateral surface (see Figure 94-7). In humans, the most important of the apical-surface transporters appears to be URAT1 (gene, *SLC22A12*). URAT1 acts as a urate/anion exchanger to transfer urate from the tubule lumen to the epithelial cytosol. The major inorganic counter-ion for URAT1 activity is Cl^- . However, organic anions such as lactate, pyrazinoate, and nicotinate can substitute for chloride, with potential clinical consequences as discussed later. The importance of URAT1 to renal urate resorption is indicated by the fact that patients with inactivating mutations of URAT1 excrete nearly 100% of their filtered urate and demonstrate low serum urate levels (along with increased urinary uric acid levels and risk for uric acid kidney stones).⁵¹⁻⁵³ Moreover, several well-established urate-lowering drugs including probenecid, benzbromarone, and losartan act by inhibiting URAT1. Conversely, other mutations in the URAT1 gene appear to convey a risk for increased urate resorption and hyperuricemia, presumably through a gain-of-function mutation.

OAT4 (gene, *SLC22A11*) and OAT10 (gene, *SLC22A8*) are two other apical anion transporters involved in renal uric acid resorption. Like URAT1, OAT10 is an anion exchange transporter; counter-ions that can promote urate transport by OAT10 include lactate, pyrazinoate, and nicotinate, a fact of clinical importance (see later). In contrast,

although OAT4 also transports urate from the tubular lumen to the cytosol of renal epithelial cells, the counter-ions it employs tend to be dicarboxylates.^{49,54}

Urate transport by URAT1, OAT4, and OAT10 would lead to accumulation of urate intracellularly and presumably to gradients that would eventually impair further urate uptake if a mechanism did not exist to transport intracellular urate out of the cell at the basolateral surface. This function appears to be served by Glut9a (gene, *SLC2A9*; also confusingly known as *URATv1*), which was first identified as a glucose transport family protein but has little or no glucose transport capacity. Instead, Glut9a is an effective transporter of urate from the renal epithelial cell out into the renal interstitium.^{55,56} A number of different inactivating mutations of Glut9a have been identified in both humans and mice; in each case the result is impaired urate resorption, increased urate excretion, and hypouricemia.^{55,57-61} Glut9a and its splice variant, Glut9b, are also expressed on other cells including chondrocytes, leukocytes, intestinal cells, and hepatocytes; the role of Glut9 proteins on these cells is actively being explored.^{62,63}

Urate Secretion. Other transport proteins in the renal tubule epithelium regulate the excretion of urate from the peritubular fluid into the tubular lumen (see Figure 94-7). At the basolateral surface, OAT1 and OAT3 (genes, *SLC22A6* and *SLC22A8*, respectively) transport urate from the interstitium into the epithelial cell cytosol. These transporters act via exchange with dicarboxylate anions and

transport not only urate, but other organic anions and some drugs.⁶⁴ At the apical surface of proximal tubule cells, two proteins have been identified that serve as urate-extruding transporters. The multidrug resistance protein MRP4 (gene, *ABCC4*) mediates ATP-dependent urate transport.⁶⁵ Whether energy failure promotes hyperuricemia by impairing MRP4 has not been established but would seem plausible. ABCG2 (gene, *ABCG2*) also directly mediates urate excretion.^{66,67} Genetic association studies have implicated two other anion transport proteins as playing a role in apical urate transport outside of the cell, namely, NPT1 (gene, *SCL17A1*) and NPT4 (gene, *SLC17A3*).^{66,68-70} Additionally, genetic studies have implicated nontransporter proteins as playing roles in urate excretion including PDZK1, CARMIL, NHERF1, SMCT1, SLC5A8, SMCT2, and SLC2A12. It is thought that some of these proteins may contribute to a macromolecular complex regulating urate transport.⁷¹

Renal Causes of Hyperuricemia

KEY POINT

Decreased renal excretion of urate, owing to intrinsic or secondary causes, results in elevated levels of serum urate.

Many patients with hyperuricemia underexcrete urate; that is, for any given serum urate level, their degree of renal urate excretion is inadequate and less than is seen in normal controls (Figure 94-8). The mechanisms of urate underexcretion are various and stem from either primary or secondary renal effects.

Primary Urate Underexcretion

In a subset of patients, hereditary defects of renal tubule urate excretion result in hyperuricemia. With the identification of the aforementioned renal urate transporters, the underlying basis for some of these defects has become apparent. For example, up to 10% of gout cases in white Europeans may be attributable to hyperuricemia induced by defects in the urate exporter ABCG2.^{66,67} Gain-of-function mutations of other transport-related proteins (e.g., PDZK1, CARMIL, NHERF1) may actually promote tubular urate resorption mediated by URAT1 activity. Patients with such intrinsic tubular defects leading to net urate underexcretion frequently display normal renal filtration and normal serum creatinine levels.

Familial juvenile hyperuricemic nephropathy (FJHN), also known as *medullary cystic kidney disease* (MDCK), constitutes a group of autosomal dominant disorders characterized by early hyperuricemia and progressive chronic kidney disease.⁷² The hyperuricemia typically precedes the renal insufficiency and is considered to be primary. Three variants are recognized, designated MDCK 1, 2, and 3. In MDCK2, mutations in the uromodulin gene result in underproduction and/or misproduction of uromodulin (Tamm-Horsfall protein), the most prevalent protein secreted by the kidney.⁷³⁻⁷⁵ The probable importance of uromodulin deficiencies to FJHN has recently been underlined by the observation that although patients with the MDCK1 and 3 subtypes of FJHN have mutations that are not in the uro-

modulin gene, they nevertheless display a phenotype of decreased uromodulin expression.⁷⁶ The mechanisms through which uromodulin deficiencies predispose to hyperuricemia are not yet understood, but mice transgenic for human uromodulin mutations develop renal tubular abnormalities and concentrating defects.⁷⁷

Secondary Causes of Renal Urate Underexcretion

A large number of underlying causes can result in nephrogenic retention of urate and subsequent hyperuricemia. These include acute or chronic renal failure, the effects of toxins and drugs, and systemic illnesses that alter renal urate handling directly or indirectly.⁷⁸

Age and Gender. Classic studies by French and colleagues⁷⁹ documented that serum urate levels tend to be low in children. In males, urate levels increase precipitously at puberty, a time when females experience only a slight increase in serum urate. For women, a gradual increase over the subsequent years, followed by another rise at menopause, finally brings the serum urate near to that of men, consistent with Hippocrates' astute aphorisms that "a young man does not take the gout until [around the time] he indulges in coition" and that "a woman does not take the gout, unless her menses be stopped."^{79,80} This discrepancy between men and women, in the period between puberty and menses, suggests strongly that sex hormones play a role in urate regulation. Indeed, studies suggest that in women, estrogenic hormones may promote renal urate excretion.⁸¹

Figure 94-8 Plasma uric acid versus renal urate excretion in underexcretors versus normal controls. The red line and symbols represent urate underexcretors; the blue line and symbols represent normal controls. For any given plasma urate level, the urate underexcreting patients demonstrate a lower degree of urinary urate; they thus require higher serum urates to produce urate-comparable urate excretion. (Large and small circles represent mean and representative individual data for the experiment, respectively.) $U_{ur}V$, urine urate excretion rate. (From Wyngaarden JB: *Gout*, Adv Metabol Dis 2:2, 1965.)

Conversely, an active role for androgens in promoting hyperuricemia may be inferred from Hippocrates' assertion that "Eunuchs do not take the gout" and from studies indicating that androgens and estrogens have opposing effects on renal organic anion transporters.⁸² In pregnant women, increases in serum urate levels are characteristic of pre-eclampsia, a reproductive emergency consisting of hypertension and proteinuria. The hyperuricemia of pre-eclampsia is thought to result from that condition's renal dysfunction; hyperuricemia in pre-eclampsia does not lead to gout but is considered by some investigators to secondarily contribute to pre-eclamptic renal dysfunction.⁸³

Systemic Illnesses (Table 94-1). Renal insufficiency (i.e., reduction in glomerular filtration rate), whether acute or chronic and for whatever reason, promotes urate underexcretion and hyperuricemia. The mechanisms of hyperuricemia in patients with renal insufficiency are complex but depend first and foremost on decreased delivery of a filtered urate load to the renal tubule. At high levels of azotemia such as are rarely seen in this era of dialysis (blood urea nitrogen >100 mg/dL), hyperuricemia is practically universal. Lesser degrees of renal failure are more variably accompanied by hyperuricemia because decreases in glomerular filtration rate (GFR) promote some compensatory increase in renal tubule urate secretion. The effects of renal insufficiency on hyperuricemia may be more apparent in patients who also possess other risk factors for elevated urate

levels. An association between congestive heart failure and hyperuricemia has also been reported. Although the effect direction of this relationship has not been well established, it is likely that the reduced renal perfusion seen in congestive heart failure can promote urate retention.

Various forms of organic (metabolic) acidoses may promote renal underexcretion of urate. Thus patients suffering lactic acidosis (e.g., in hypoxia, sepsis, liver or kidney disease, postsurgery or myocardial infarction, during excessive anaerobic exercise, or in response to certain drugs such as metformin) may become hyperuricemic. Similarly, patients experiencing ketoacidosis (e.g., alcoholic or diabetic ketoacidosis, starvation ketosis) may also develop hyperuricemia. Lactic acidosis may also occur secondarily to ketoacidosis. Although the mechanisms of these effects were previously considered to result from direct competition between the organic acids and urate for tubular excretion, they are probably better considered from the perspective of recent discoveries in renal urate transport (described earlier). In particular, organic acids serve as exchange anions for the apical surface renal urate transporters URAT1 and OAT10. Such acids therefore provide a motive force for increased urate resorption in the proximal tubule.

Dehydration (volume depletion) on any basis promotes hyperuricemia.⁸⁴ Once again, the mechanisms are complex but include decreased renal perfusion and subsequently decreased urate filtration and delivery to the proximal tubule. Subsequent sodium retention will reduce tubular urate secretion, probably at the Na⁺/urate co-transporters NPT1 and NPT4. Patients exposed to low-sodium diets may also retain urate in an effort to retain sodium.

Several metabolic and/or endocrinologic conditions have been associated with hyperuricemia, although whether these represent independent associations has not been determined. These include hypothyroidism and hyperthyroidism, and hypoparathyroidism and hyperparathyroidism. Obesity is associated with hyperuricemia,⁸⁵ and weight loss has been shown to reduce both serum urate levels⁸⁶ and risk of gout.⁸⁷ Although it is conceivable that adiposity itself may promote hyperuricemia, this relationship is complex because adiposity may also reflect diet and thyroid status. Patients who have undergone renal transplant experience increases in prevalence of hyperuricemia and gout (2% to 13%). It is likely that the hyperuricemia in renal transplant patients is not related to the transplant per se, but to other factors such as intrinsic renal insufficiency, diuretic use, and especially the use of cyclosporine to suppress rejection (discussed further later).⁸⁸ Reciprocally, some studies suggest that hyperuricemia in transplant patients may contribute to worsening renal function.

Drugs (Table 94-2). Diuretics are among the most commonly used agents to treat hypertension and congestive heart failure, and it has long been appreciated that many diuretics promote hyperuricemia and subsequent gout.^{89,90} Despite early assessments suggesting otherwise,⁹¹ the increase in gout risk owing to diuretic use is substantial and may range as high as 3- to 20-fold.⁹² The mechanisms through which diuretics raise serum urate are incompletely elucidated but include the induction of sodium wasting and volume depletion, with a resultant decrease in the fractional excretion of urate.⁹³ However, individual diuretics may also have more specific and direct effects on renal urate

handling. For example, loop diuretics such as furosemide and bumetanide interact directly with the tubular urate transporter NPT4,⁷⁰ and both thiazide and loop diuretics inhibit the renal urate exporter MRP4.⁹⁴ Indeed, despite the volume-depleting effects of diuresis, not all diuretics promote hyperuricemia. For example, the potassium-sparing diuretics triamterene, amiloride, and spironolactone do not raise urate. Interestingly, some diuretics actually lower serum urate levels, apparently by directly promoting renal urate excretion even as they induce volume depletion. One such drug was tienilic acid, an effective diuretic and anti-hyperuricemic that was withdrawn from use owing to hepatotoxicity.

Several drugs that are weak organic acids may raise serum urate by serving as counter-ions to promote urate retention by URAT1 and OAT10. These drugs have also been assumed to inhibit tubular secretion, possibly by acting as urate competitors. Among these agents is the lipid-lowering drug nicotinic acid, which may not only block urate secretion but also promote urate formation.⁹⁰ Low-dose salicylates including the low doses of aspirin used for cardioprotection may also raise urate by impairing renal urate efflux.⁹⁴ At high doses salicylates become uricosuric, apparently through the inhibition of URAT1.⁹⁵ The antituberculous agent pyrazinamide is the most potent urate-retaining agent known.⁹⁰ Pyrazinamide is metabolized to pyrazinoate and subsequently to 5-hydroxypyrazinoate⁹⁶; it is likely that these organic anions act in a manner similar to nicotinate and salicylate. Another antituberculous agent, ethambutol, can also reduce renal tubular urate excretion and promote hyperuricemia. However, the mechanism of ethambutol's action is not well established.⁹⁷

The immunosuppressant cyclosporine is well known to promote decreased renal urate excretion and hyperuricemia. The mechanism of cyclosporine-induced hyperuricemia is presumed to depend, at least in part, on the common cyclosporine effect of decreasing renal glomerular filtration; reciprocally, hyperuricemia may exacerbate the nephrotoxic cyclosporine effects.⁹⁸ However, tacrolimus, whose mechanism of immune action is not dissimilar to that of cyclosporine, and which also can impair renal function, does not promote similar hyperuricemia. Moreover, cyclosporine's effect on urate retention appears to exceed its effects on renal filtration, suggesting a probable direct effect on tubular urate transport.^{90,99} Most studies of cyclosporine's effects on urate have been performed in patients who have undergone

renal transplant; cyclosporine's effects on urate in other settings are less well established.

Toxins. Several toxins can affect the kidney to promote hyperuricemia. Chief among these is lead. Lead exposure is endemic to Western society, but there have been a number of periods during which lead exposure may have been excessive (e.g., during the Roman Empire). A connection between lead exposure, hyperuricemia, and gout has been suspected at least since the 18th century.¹⁰⁰ In the 20th century, a large cohort of patients with lead-induced hyperuricemia (saturnine gout) was recognized during and after the era of Prohibition, predominantly in the Southeastern United States and relating to the home brewing of whiskey (moonshine, or white lightning) using lead-lined vessels (typically, automobile radiators). Lead consumption results in distribution to a reservoir in bone and may have adverse effects on the central nervous system as well. In the kidney, lead poisoning leads to interstitial and perivascular fibrosis, as well as glomerular and tubular degeneration.^{101,102} Although patients with lead nephropathy do experience mild to moderate renal insufficiency, their clearance of urate is excessively limited, indicating a tubular defect in urate excretion.¹⁰³ Suggestions that lead exposure may also promote purine turnover are provocative but have been less well supported.¹⁰⁴ Although saturnine gout is currently a relatively rare condition, epidemiologic data suggest that it may be more prevalent than commonly assumed.¹⁰⁵ In patients with moonshine nephropathy, associated lifestyle factors (e.g., alcohol consumption, obesity) may play a significant role in the genesis of the hyperuricemia.¹⁰⁶

Patients with chronic beryllium poisoning, usually as a result of an occupational exposure, may also suffer diminished renal urate excretion and hyperuricemia.¹⁰⁷

Diet and Uric Acid

KEY POINT

Diet can have significant effects on serum urate levels, both by serving as a source of dietary purines and by altering the metabolic production and/or renal excretion of uric acid.

A number of dietary components can affect serum urate levels, mainly by leading to urate overproduction. Several other dietary components may have the capacity to lower serum urate levels.

Purine-Rich Foods

Purine-rich foods comprise a major source of daily purine load and hence a major source of generated urate. However, not all purine-rich foods convey equivalent risk: seafood and red meat, particularly organ meats, convey an increased risk for hyperuricemia, whereas consumption of purine-rich, leafy-green vegetables apparently does not.¹⁰⁸ Earlier authors emphasized the limited effect of purine intake, with studies suggesting that alterations in purine intake may result in, at most, changes in serum urate of about 1 mg/dL.^{78,109} However, such studies have rarely accounted for the role of renal urate excretion in the context of diet. Thus it is worth considering whether, for a patient who is intrinsically

unable to excrete serum urate, an increased dietary purine load may produce more profound increases in serum urate levels than would be seen in a patient with normal excretory capacities.

In contrast to purine ingestion, protein consumption does not increase the risk of hyperuricemia and/or gout, a point of occasional confusion for practitioners, because many high-purine foods are also high in protein.¹⁰⁸

Fructose

Osler recognized the ability of fructose to provoke gouty attacks as early as 1901.¹¹⁰ Little was made of this observation, however, until the 1960s and 1970s, when it was demonstrated that fructose loads, administered orally or intravenously, cause transient rises in serum urate levels, particularly in gout patients.^{111,112} These effects are reproduced with consumption of sucrose (which contains fructose), but not glucose or galactose. Biochemical analysis of fructose metabolism has provided insight into the mechanisms of fructose-induced hyperuricemia (Figure 94-9). The first step in fructose metabolism (not shared with glucose or galactose) is the donation of a phosphate from ATP to form fructose-1-phosphate (enzyme phosphofructokinase), generating ADP. ADP is then converted to AMP (enzyme adenylate kinase), which in turn can be degraded via several steps to uric acid. In addition, fructose in effect serves as a phosphate “sink” because the donated phosphate is no longer available for the regeneration of ATP from AMP and ADP. Because both P_i and ATP inhibit the purine degradation pathway (inhibition of AMP deaminase and 5′ nucleotidase, respectively), depletion of these compounds promotes the formation of uric acid as well.¹¹³ Depletion of ADP/AMP may also impair feedback inhibition and promote purine biosynthesis. Epidemiologic studies confirm a role for fructose consumption in hyperuricemia; patients who consume excessive fructose in the form of fructose-sweetened soft drinks or fruit juices demonstrate both higher serum urate levels and increased incidence of gout.¹¹⁴⁻¹¹⁷ The

probable importance of fructose may be underscored by the fact that the rise in gout prevalence over the past several decades has occurred in parallel with an increased industrial use of fructose, rather than dextrose (glucose), as a major additive in soft drinks and prepared foods.

Alcoholic Beverages

Ethanol ingestion is associated with incidence of gout, and ample physiologic and epidemiologic data confirm that ethanol consumption promotes the development of hyperuricemia.¹¹⁸⁻¹²² Ethanol is a particularly effective agent for raising serum urate levels because it works through multiple mechanisms. Chief among these is the requirement for ATP degradation during ethanol metabolism, resulting in increased purine turnover and urate generation.^{123,124} The ability of binge alcohol consumption to induce increases in lactate levels also contributes to hyperuricemia by decreasing renal urate excretion, likely through effects on URAT1 as discussed earlier.^{125,126} Ethanol consumption also promotes a diuresis, probably via antidiuretic hormone suppression¹²⁷; as noted earlier, dehydration and volume depletion can promote renal urate retention. At high levels of acute-on-chronic alcohol consumption ketoacidosis may ensue, particularly in the setting of transient starvation and/or vomiting¹²⁸; in such settings uric acid secretion may be inhibited, or uric acid resorption promoted by 3-hydroxybutyrate and acetoacetate, in much the same manner as lactic acid.¹²⁹ As a dietary matter, some alcoholic beverages, particularly beers and ales, are high in purines, mainly in the form of guanosine. Indeed, consumption of ethanol-free beer derivatives transiently raises serum urate levels, although not to the extent of beer itself.¹³⁰ The importance of purine load in alcoholic beverages may be underlined by the fact that, in contrast to beer, moderate wine consumption (<2 glasses/day) does not appear to increase serum urate levels.^{122,131} As noted earlier, saturnine gout contracted from lead-adulterated moonshine may also contribute to ethanol-induced hyperuricemia.

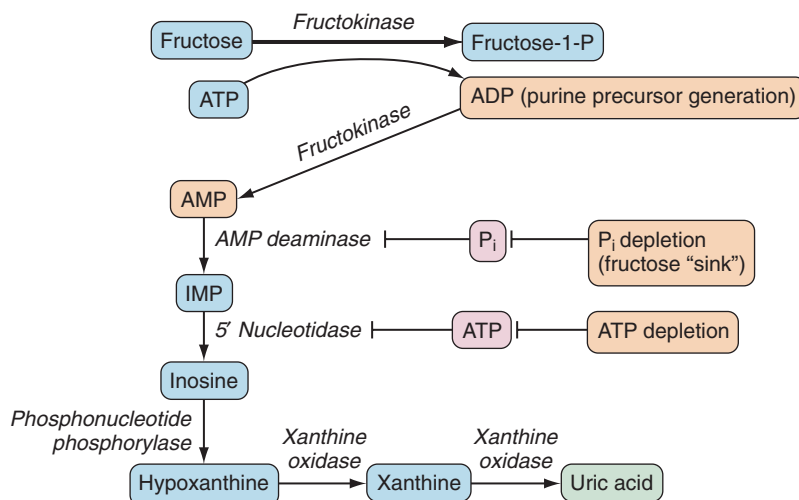

Figure 94-9 Fructose and the generation of uric acid. Ingested fructose is converted to fructose-1-phosphate, a process that uses adenosine triphosphate (ATP), generates adenosine diphosphate (ADP), and sequesters inorganic phosphate (fructose/phosphate “sink”). The ADP generated then serves as a substrate for urate generation, while the depletion of ATP and P_i results in decreased feedback inhibition of the enzymes that mediate uric acid synthesis. AMP, adenosine monophosphate; IMP, inosine monophosphate.

Other Dietary Components

Recent data, both epidemiologic and physiologic, indicate that consumption of low-fat dairy products is independently associated with reduced serum urate levels and risk of gout.¹⁰⁸ In physiologic studies, consumption of milk or milk proteins has a direct uricosuric effect that results in serum urate lowering.¹³² Interestingly, dairy products may also have anti-inflammatory effects.¹³³ Regular heavy coffee consumption (4 to 6 cups daily) may have urate-lowering properties that are independent of caffeine¹³⁴⁻¹³⁶; these effects appear to be concordant with a reduced risk of incident gout.¹³⁷ In contrast, intermittent coffee consumption may be transiently prohyperuricemic, possibly as a result of caffeine-induced diuresis and volume depletion. Increased intake of vitamin C has been associated with decreased serum urate levels, possibly via a uricosuric effect.¹³⁸

CRYSTAL FORMATION: THE TRANSITION FROM HYPERURICEMIA TO GOUT

KEY POINT

Monosodium crystal formation involves physicochemical processes but may be regulated by synovial fluid proteins and immunoglobulins.

Soluble urate does not induce gouty attacks; only crystallized urate promotes acute inflammation. Urate crystallization is therefore a critical step in the progression from hyperuricemia to frank gout.¹³⁹

Uric acid is a weak organic acid (pKa1 of 5.75 [position 9] and pKa2 of 10.3 [position 3]). At physiologic pH (7.4), approximately 98% of uric acid exists in the form of monosodium urate (MSU) monohydrate. At concentrations greater than 6.8 mg/dL, MSU exceeds its apparent solubility limit in serum, the definition of hyperuricemia. Exceeding the urate solubility threshold potentiates the precipitation of needle-shaped crystals and results in inflammatory responses. However, Sir William Roberts recognized that not all patients with hyperuricemia developed gout and drew a distinction between hyperuricemia and the crystallization of MSU.¹⁴⁰ Epidemiologic studies also suggest that urate crystal formation and consequent development of acute gout may occur in a minority of subjects with hyperuricemia.¹⁴¹ Therefore factors other than hyperuricemia must influence the formation of urate crystals.

In vitro models have shed light on the relationship between urate crystallization and environmental factors such as pH, temperature, salt content, vibration, and large molecules.¹⁴²⁻¹⁴⁴ The fact that urate may more readily precipitate at both lower pH and lower temperature, for example, provides a possible rationale for the fact that gout attacks are most commonly seen in the first metatarsophalangeal joint, a joint that is both circumferentially exposed (i.e., relatively low in temperature) and at the farthest point of the systemic circulation.

Given that crystal formation and gouty attacks most commonly occur within the confines of the joint, other investigators have emphasized a possible role for joint biology per se in the formation of MSU crystals. For example,

some investigators have suggested that soluble urate is excreted more slowly from the joint than other serum elements, providing a possible mechanism for urate concentration within the joint space.¹⁴⁵ Once urate crystals are formed, the fenestrated endothelium of the synovium might permit the joint space to serve as a crystal “trap,” preventing crystals from being dispersed and/or dissolved in the wider circulation. Other investigators have emphasized the possible role of cartilage itself in the precipitation of urate, particularly in the setting of aging and/or osteoarthritis.¹⁴⁶ Potential mechanisms through which aging cartilage might facilitate MSU nucleation/crystallization include changes in the proportions and/or chemical properties of cartilage glycoaminoglycans and proteoglycans, as well as increases in intracellular and extracellular lipid content of articular cartilage.¹⁴⁶⁻¹⁴⁸ One recent report suggests that osteoarthritis chondrocytes may actually secrete urate into the joint space, promoting local urate excesses in the synovial fluid.¹⁴⁹

Several investigators have suggested that urate crystallization may be an immune-assisted process. Kam and colleagues¹⁵⁰ proposed that IgG antibody-binding to MSU monomers, previously assumed to be nonspecific, may permit the stacking of MSU crystals to occur despite dispersion forces that exist in fluid and tissue. More recently, Kanevets and colleagues¹⁵¹ postulated a role for urate crystal-specific IgM antibodies in the nucleation and formation of urate crystals.

Although urate precipitation is the sine qua non of acute gout, not all urate precipitation may lead directly to acute gouty arthritis. Imaging studies confirm that, in patients with asymptomatic hyperuricemia, urate crystals may nonetheless deposit in both cartilage and synovium.¹⁵² These deposits are of consequence not only for their potential to directly damage tissue (see Chronic Tophaceous Gout later) but also for their role as a reservoir of uncoated and potentially inflammatory urate crystals. Thus local trauma, long recognized as a possible antecedent to acute gouty attacks, may physically release cartilage-deposited crystals into the joint space, where they can initiate inflammation. In addition, the acute lowering of serum and synovial fluid urate levels (e.g., during initiation of urate-lowering drugs) is well documented to precipitate gouty attacks¹⁵³ by a mechanism that is most likely akin to that in which glacial melting causes the sloughing off of icebergs and the exposure of previously hidden surfaces.

ACUTE GOUT ATTACKS: THE INFLAMMATORY RESPONSE TO MONOSODIUM URATE CRYSTALS

KEY POINT

Uric acid crystals activate both complement and resident synovial leukocytes, inciting neutrophil influx that itself promotes further inflammation.

Uric acid in its crystalline form is a potent trigger of inflammation. The phlogistic potential of crystalline urate in human gout was established dramatically in the 1960s by Faires and McCarty, who self-injected urate crystals into their knee joints and subsequently experienced attacks of

acute inflammation.^{154,155} In the clinic, the diagnosis of gout is made on joint aspiration, when examination of synovial fluid under polarized light microscopy demonstrates the presence of urate crystals, neutrophils, and particularly intracellular urate crystals, confirming directed neutrophil phagocytic activity.¹⁵⁶ However, the inflammatory mechanisms of gout are complex and involve not only neutrophils but other cell types, numerous inflammatory mediators, and well-organized sequences of events.¹⁵⁷

Uric Acid Crystals and Complement Activation

Complement activation by the alternative pathway is a continuous process in body fluids, in which C3 component activation in the fluid phase is followed by rapid C3b deposition onto nearby surfaces.¹⁵⁸ On most cell surfaces C3 is routinely inactivated by regulatory proteins. In contrast, the polyanionic surfaces of uric acid crystals provide opportunities for unconstrained C3 deposition and subsequent activation of downstream complement components. Weissmann and others^{159,160} have demonstrated the ability of urate crystals to activate complement from C2-depleted serum, confirming activation of the alternative pathway. Interestingly, other groups have confirmed that uric acid crystals also activate complement by the classical pathway (i.e., via C1 activation). Crystal activation of the classical pathway may occur in two ways. First, uric acid crystals may activate the classical pathway by an immunoglobulin-independent, C-reactive protein (CRP)-dependent pathway.^{159,161,162} In addition, it has been shown repeatedly that urate crystals possess the ability to bind antibodies. The specificity of IgG binding, as well as the question of whether antibodies bound to urate crystals can lead to additional activation of the classical pathway, is not fully resolved.^{159,162,163} One result of crystal-induced complement cascades is to produce C5a, a potent vasodilator and chemoattractant for inflammatory cells such as neutrophils.^{164,165} A study by Tramontini and colleagues suggests that urate crystal complement activation may also lead to generation of soluble complement membrane attack complexes, which may activate local cells to promote inflammation.¹⁶⁵ Other proteins of potential import to inflammation including fibronectin and kininogen may also adhere to urate crystals.¹⁶⁶

Cellular Response to Crystals

Cell Recognition of Crystalline Urate

MSU crystals interact with, and potently stimulate, a range of inflammatory cells. How crystals activate cells remains an open question, but three major mechanisms have been proposed: (1) crystal recognition via Toll-like receptors (TLRs), (2) interactions between urate crystals and cholesterol rafts in the cell membrane, and (3) direct phagocytic mechanisms.

TLRs are critical for innate immunity and permit organisms to rapidly recognize bacteria and viruses on the basis of stereotypical features (pathogen-associated molecular patterns [PAMPs]), rather than characteristics unique to the specific invader. Because crystalline urate might theoretically be treated as a foreign molecule, several investigators have examined whether urate crystals can activate TLRs.

In TLR2- and TLR4-knockout mice, decreased IL1- β and tumor necrosis factor (TNF) production, as well as decreased neutrophil influx in the air pouch inflammation model, argue strongly for a role for TLRs in urate crystal responses.¹⁶⁷ Impairment of urate-driven inflammation in CD14 knockout mice also appears to support a role for TLRs (CD14 is essential for TLR2- and TLR4-dependent signaling).¹⁶⁸ Interestingly, Joosten and colleagues suggest that TLR2 activation by MSU crystals requires simultaneous exposure of the receptors to C18:0 free fatty acids, suggesting a synergistic effect.¹⁶⁹ However, other researchers have observed no effect of multiple TLR knockouts on murine models of urate-induced inflammation.¹⁷⁰ The role of TLRs in urate signaling therefore remains something of an open question.

Other authors have emphasized the ability of MSU crystals to electrostatically interact with cholesterol.¹⁷¹ Cholesterol-rich regions of plasma membranes (lipid rafts) are characteristically rich in signaling molecules and represent hot spots for cellular activation. Receptor-independent interactions between crystalline MSU and lipid rafts have been demonstrated in dendritic cells, resulting directly in cell activation. The mechanism behind this effect appears to relate to hydrogen bond-dependent aggregation of lipid rafts; aggregation of transmembrane receptors within the rafts then results in activation of immunoreceptor tyrosine-based activation motifs (ITAMs), followed by activation of the signaling molecule Syk.^{172,173} Syk activation in turn can induce cell activation including phosphoinositol-3 (PI-3) kinase signaling, cytoskeletal rearrangement, and crystal phagocytosis.

As noted earlier, MSU crystals may become coated by immunoglobulins and other serum proteins and may serve as a substrate for complement activation. Thus protein-coated urate crystals may also activate cells via their ability to engage immunoglobulin, complement, and possibly other cell surface receptors. Consistent with this model, IgG- but not IgM-coated urate crystals have been observed to incite greater inflammatory responses than those that are uncoated.¹⁷⁴

Intracellular Responses to Urate Crystal Encounters

Activation of cells by urate crystals results in the activation of a number of intracellular signaling molecules associated with inflammatory responses. In addition to Syk, these include PI-3 kinase; the ERK, JNK, and p38 mitogen-activated protein (MAP) kinases; phospholipases C and D; rho-family proteins; and nuclear factor κ B (NF κ B). Depending on the cell type in question, activation of these molecules will result in specific phenotype alterations including cytoskeletal alterations, production of cytokines and lipid mediators, and induction of phagocytosis and superoxide generation.¹⁷⁵⁻¹⁸⁰ Additional responses, secondary to these initial ones, include vasodilation and vascular leakiness, the upregulation of adhesion molecules on endothelial and inflammatory cell surfaces, and cellular chemotaxis, discussed later.

It has long been appreciated that urate crystals can induce macrophages to produce IL-1 β and that IL-1 β so produced is central to the development of gouty inflammation.¹⁷⁶ However, the mechanism of urate-induced IL-1 β

upregulation remained, until recently, unknown. The NLRP3 (formerly NALP3, CIAS1, or cryopyrin) inflammasome is a multimolecular, cytosolic complex whose primary purpose is to generate IL-1 β , as well as IL-18 and IL-33 (see also Chapter 18).¹⁸¹ The pro form of IL-1 β is cleaved into activated IL-1 β by the inflammasome-associated enzyme caspase-1, which may also play a role in IL-1 β secretion. In a seminal study, Martinon and colleagues¹⁸² documented the ability of MSU crystals to activate the NLRP3 inflammasome and stimulate IL-1 β generation (Figure 94-10). Subsequent inflammatory responses (e.g., TNF production) appear to occur secondary to autoengagement of cell surface IL-1 β receptors. The importance of the inflammasome in crystal inflammation has been well documented in mouse models: Macrophages from mice lacking inflammasome components generate diminished levels of IL-1 β on MSU crystal exposure, and intraperitoneal injection of urate crystals into inflammasome-deficient mice, as well as mice deficient in IL-1 β receptors, leads to significantly decreased neutrophil recruitment.¹⁸² Moreover, the ability of IL-1 β -directed therapies to abrogate both human gout and murine crystal-induced inflammation speaks to the centrality of IL-1 β in the inflammatory response to urate crystals.¹⁸³

To date, there is no definitive explanation as to how urate crystals activate the NLRP3 inflammasome. Leading theories center on the inflammasome as an internal sensor for cell stress resulting from either (1) oxidative stress or shifts in ion concentration, and/or (2) lysosomal disruption.^{184,185} In one proposed model, crystal-induced damage

to the plasma membrane promotes cellular potassium efflux and the resultant hypokalemic state activates the inflammasome directly.¹⁸⁶ Additionally, crystal activation of the phagocyte NADPH oxidase leads to the generation of reactive oxygen species (ROS), which may then be directly or indirectly sensed by the inflammasome. The ability of large urate crystals to provoke incomplete or frustrated phagocytosis—in which a phagocyte surrounds but cannot fully engulf a target—may lead to an activated state (including oxidase activation) that also contributes to inflammasome activation.¹⁸⁴ The second proposed mechanism of inflammasome activation by MSU crystals is based on the ability of phagocytosed urate crystals to rupture the membranes of phagolysosomes, either by mechanical or physicochemical effects.¹⁸⁷ Phagolysosome rupture would lead to cytosolic acidification and intracellular release of cathepsin B, each of which has been proposed as a NLRP3 inflammasome activator.¹⁸⁵ These various mechanisms may not be mutually exclusive and may act synergistically (e.g., lysosomal disintegration and cathepsin-B release may themselves promote the production of ROS).

Initiation and Propagation of the Acute Gouty Attack

The clinical picture of acute gout is one of rapid, almost explosive development of an inflammatory response. Accordingly, cellular changes during the acute attack must reflect the accelerating nature of the inflammation.

Figure 94-10 Activation of the NOD-like receptor family, pyrin domain containing 3 (NLRP3) inflammasome by monosodium urate crystals. Activation of the inflammasome by urate crystals results in activation of caspase-1, which cleaves and activates interleukin-1 β (IL-1 β) and promotes IL-1 β secretion. In turn, IL-1 β can engage its receptors to secondarily promote the synthesis and secretion of other cytokines such as tumor necrosis factor (TNF) and IL-6. Three possible mechanisms of inflammasome activation by urate crystals are illustrated: (1) production of reactive oxygen species (ROS), (2) activation of Toll-like receptors 2 and 4 (TLR2/4), and (3) potassium depletion, which may be sensed by the inflammasome. The precise roles of these and other mechanisms of inflammasome activation by urate crystals remain a matter of investigation. ASC, apoptosis-associated speck-like protein containing a caspase-recruitment domain.

Figure 94-11 Initial phases of urate crystal-induced activation. The presence of “fresh” urate crystals, resulting either from spontaneous precipitation or the liberation of crystals from established pools, results in direct complement activation and activation of resident cells in the synovium including macrophages, fibroblasts, and mast cells. Activated cells produce interleukin-1 β (IL-1 β) and other cytokines, as well as multiple other mediators (not all illustrated) that in turn activate both bloodstream neutrophils and endothelial cells. Not illustrated, these responses permit neutrophils to adhere to and traverse the endothelium, resulting in neutrophil influx and the further propagation of inflammation as neutrophils undergo direct activation by urate crystals. See text for additional details.

Beginning with the appearance/release of urate crystals, the initial phase of gouty inflammation must depend on already-available local mediators, as well as cells that are both (1) capable of urate responses and (2) already in place within the joint. Clearly, immunoglobulin binding and the activation of complement on the crystal surface must be one such early response. Interaction of the crystal with local tissue cells, facilitated in part by IgG and complement opsonization, is also likely to play an early role. Best studied among the early cell type responses is that of the synovial macrophage, a resident cell in the synovial membrane. Macrophage activation in response to crystals results in synthesis and secretion of important cytokines such as IL-1 β , TNF, IL-6, and the chemokine IL-8 (CXCL8), as well as release of potentially tissue-destroying matrix metalloproteinases and toxic oxygen radicals.^{175,176,188,189} Activation of synovial macrophages is contemporaneous with their phagocytosis of urate crystals. Human synovial fibroblasts are also capable of responding to urate crystals, leading to the generation of both inflammatory mediators and metalloproteinases.¹⁹⁰ Finally, mast cells are also resident within the synovium and appear to be important in the early phases of acute gouty responses, as their depletion diminishes inflammation in murine models of crystal-induced inflammation.¹⁹¹ Mast cells increase in number and activity in the lining

of experimental air pouches after MSU crystal injection, suggesting that additional mast cells may be secondarily attracted to the inflammatory site (Figure 94-11).¹⁹²

These early events promote the influx of both additional bloodstream monocyte/macrophages and polymorphonuclear neutrophils, the predominant cell in the inflamed gouty joint. Cytokines and other inflammatory mediators produced in the early phase of the crystal response act on the vascular endothelium to promote vasodilation and leakiness and to upregulate the expression of adhesion molecules such as selectins and ICAMs (intercellular adhesion molecules) on the vascular surface of endothelial cell.¹⁹³ These same cytokines also promote neutrophil activation within the bloodstream, particularly the upregulation of the integrin adhesion molecule CD11b/CD18. A role for the crystal-generated complement component C5a in the activation of bloodstream neutrophils is also likely because C5a can potently stimulate CD11b/CD18 activation and neutrophil adhesiveness.¹⁹⁴ The result is that neutrophils and (in far fewer numbers) monocytes first adhere tightly to the endothelium and then exit the vasculature, followed by chemotaxis up the C5a complement gradient, leading to encounter with, and phagocytosis of, the provoking urate crystals. The mechanisms of neutrophil activation by crystals include those discussed earlier and appear to

importantly include interactions with CD11b/CD18 (which is also a complement receptor) and the IgG receptor Fc γ RIIB. Subsequent neutrophil intracellular signaling events include phosphorylation and/or activation of a number of tyrosine kinases including Lyn, Syk, Tec, and Src; activation of PI-3 kinase; and activation of phospholipase C.¹⁹⁵ Activation of MAP kinases is probably also involved because these kinases regulate neutrophil adhesion and superoxide generation.¹⁹⁴

Neutrophils encountering urate crystals can rapidly promote additional inflammation and additional neutrophil influx via several mechanisms (Figure 94-12). First, neutrophils stimulated by urate crystals generate a number of inflammatory mediators and potent neutrophil chemoattractants including IL-1 β , IL-8, leukotriene B₄ (LTB₄), S100A8/A9, prostaglandin E₂, and crystal-induced chemoattractant factor.¹⁹⁵ Of these, IL-8 and LTB₄ are potent chemoattractants. They play a particularly important role in amplifying the chemoattractant gradient and promoting additional neutrophil influx. Second, neutrophils stimulated by crystals release a wide range of products capable of directly damaging local tissues including oxygen radicals and metalloproteinases such as MMP-8. Although these mediators are intended for digestion of foreign particles within phagolysosomes, the large size of many urate crystals results in incomplete (“frustrated”) phagocytosis of the crystals, with the result that lysosomal contents are released into an unsealed phagolysosome and can escape to promote extracellular tissue damage (“regurgitation during feeding”). This process appears to be facilitated by crystals coated with immunoglobulins.¹⁷⁴ Alternatively, when uncoated crystals are phagocytosed, their ability to interact with the cholesterol-rich bilayers of the phagolysosome results in phagolysosome rupture, cellular necrosis, and direct release

of toxic neutrophil contents.¹⁸⁷ In either case, the result is the potential for tissue damage and rapidly accelerating inflammation.

Resolution of the Acute Gouty Attack

One of the more interesting features of the acute gouty attack is that, particularly in the early years of the disease, most such attacks are self-limited.¹⁹⁶ Multiple effects have been invoked to explain this phenomenon. Urate crystals may become coated with synovial fluid proteins (e.g., apolipoproteins B and E), inhibiting their ability to provoke inflammation.¹⁹⁷ In this context, it is worth noting that between acute attacks, some crystals may be present in the joint despite the absence of inflammation, suggesting the potential for such crystals to become inactive. Additional research has been focused on the clearance of crystals from the joint during the resolution phase of acute attacks, when the joint fluid crystal burden typically falls. Some authors have emphasized the ability of macrophages to clear urate crystals and of macrophages to clear apoptotic neutrophils that have ingested crystals, resulting in decreased crystal burden.^{198,199} The enzymatic products of inflammatory cells may degrade proinflammatory cytokines, and persistent receptor stimulation may result in receptor downregulation. The stress of the gouty attack may promote adrenocorticotrophic hormone (ACTH) secretion; in addition to its ability to induce glucocorticoid release, ACTH can bind directly to melanocyte-stimulating hormone receptors to provoke anti-inflammatory effects.²⁰⁰⁻²⁰²

More recent investigations have emphasized the local, active events through which inflammation may be resolved. For example, in vivo studies using the urate crystal-induced mouse air pouch model of inflammation suggest that local

Figure 94-12 Propagation of the acute gouty response by activated neutrophils. Neutrophils that enter the joint migrate toward and phagocytose crystals. In the case of crystals coated with immunoglobulins and complement, the resultant activation results in synthesis and/or release of inflammatory mediators such as interleukin (IL)-1 β , IL-8, and tumor necrosis factor, as well as proteases and reactive oxygen species. In the case of uncoated crystals, the crystal frequently interacts with, and lyses the membrane of the phagolysosome, spilling toxic contents and leading to cell lysis. In both cases, the result is local tissue damage and recruitment of additional neutrophils from the bloodstream in an explosive inflammatory cycle. LTB₄, leukotriene B₄.

upregulation of expression of PGD₂ and 15d-PGJ₂ (a spontaneous dehydration product of PGD₂) contributes to the resolution of crystal-mediated inflammation, probably through the ability of these molecules to activate the peroxisome proliferator activating receptor- γ (PPAR- γ).^{203,204} Urate crystals also stimulate the expression of PPAR- γ itself, setting the stage for enhanced suppression of inflammation. 15d-PGJ₂ inhibits secretion of IL-1 β , IL-6, and IL-12, as well as TNF from macrophages, and downregulates the expression of inducible nitric oxide synthase. Other targets of 15d-PGJ₂ include PGD receptors and the NF κ B pathway. 15d-PGJ₂ also inhibits CXC chemokine production, alters cellular adhesion molecules, and stimulates apoptosis of endothelial cells. Other anti-inflammatory molecules (e.g., IL-10) are also upregulated, and the more recently identified and potent anti-inflammatory resolvins and lipoxins are almost certainly involved.²⁰⁵

In considering the resolution of acute gouty inflammation, it is important to recognize the biologic programs that delay the production of anti-inflammatory molecules until the appropriate phase in the sequence. For example, PGD₂ and 15d-PGJ₂ production initially declines on exposure to urate crystals, apparently facilitating the inflammatory response, but then rebounds during the resolution phase.²⁰⁶ Similarly, the generation of anti-inflammatory lipoxins requires the accumulation of at least two active cell types (either neutrophils and activated endothelium, or neutrophils and activated platelets), an evolutionary adaptation that creates an intrinsic delay before the anti-inflammatory effects are initiated.²⁰⁷ Finally, a late-phase, anti-inflammatory release of TGF- β by macrophages that have phagocytosed urate crystals appears to require cellular maturation because monocytes that are newly arrived to the gouty joint generate proinflammatory rather than anti-inflammatory mediators.

Chronic Gouty Arthritis and Tophaceous Gout

The natural history of gout may include eventual progression to a state characterized by chronic inflammation and/or the establishment of macroscopic urate deposits known as *tophi*. Even during the asymptomatic, intercritical periods of gout, low-grade chronic inflammation can persist, with continuous phagocytosis of crystals by leukocytes.²⁰⁸ In patients with longstanding gout, intercritical inflammation can become frankly apparent and the cytokines, chemokines, proteases, and oxidants that participate in acute inflammation can contribute to chronic synovitis, cartilage loss, and bone erosion, signaling the progression to chronic gouty arthritis.²⁰⁹

Although tophi are composed primarily of MSU crystals, they are complex structures in which urate (1) is embedded in a matrix of lipids, proteins, and mucopolysaccharides and (2) drives a persistent inflammatory state.¹⁴⁷ A tophus can alternatively be conceived of as a granuloma of mononucleated and multinucleated macrophages arranged in three distinguishable zones. MSU crystals and debris constitute the central zone. Surrounding the central zone is the corona zone, consisting of macrophages, mast cells, and plasma cells. This biologically active corona is thought to account for the ultrasonographic finding of an anechoic rim that circumscribes a tophus.²¹⁰ Eventually, the corona and

central zones may become encased by a connective tissue layer, the fibrovascular zone. Within this zone, macrophages express surface markers of recent migration, maturation, apoptosis, continuous recruitment, and proinflammatory activation.^{211,212}

Tophi are important not only for their role as reservoirs of crystalline urate but also for their ability to damage the tissues in which they reside (see Figure 95-6). Mechanical factors, induction of lytic enzymes, and synthesis of proinflammatory cytokines all contribute to the tophus's ability to promote erosion and joint destruction.¹⁴⁶ Tophus macrophages produce IL-1 β , TNF, IL-6, IL-17, matrix metalloproteinases (MMP)-2, and MMP-9, and macrophage colony-stimulating factor (M-CSF).²¹¹ These molecules promote further inflammation and tissue damage, as well as promote the maturation and activation of osteoclasts that actively resorb bone. For example, M-CSF interacts with M-CSF receptors on osteoblast progenitor cells to promote osteoclastogenesis. Tophus expression of IL-1 β and other cytokines has been shown to decrease the anabolic effects of osteoblasts by decreasing the 1,25-dihydroxyvitamin D₃-dependent activity of alkaline phosphatase and osteocalcin.²⁰⁹ Both IL-1 β and TNF may directly promote bone erosions through the elucidation of matrix metalloproteinases and may also upregulate the RANK/RANK ligand system, the major promoter of osteoclastogenesis and osteoclast activation. Additionally, MSU crystals on the cartilage surface activate chondrocytes to release IL-1 β , nitric oxide, and MMPs, causing further joint damage and cartilage destruction. Even in asymptomatic patients, the inflammatory and erosive processes persist; damage may not be apparent until late in the process.

NONGOUT EFFECTS OF HYPERURICEMIA

KEY POINT

Even in the absence of gout, hyperuricemia and soluble serum urate are biologically active and may have previously unappreciated clinical effects.

In addition to its roles in acute and chronic gouty arthritis, hyperuricemia may have other adverse as well as beneficial effects. Several investigators have demonstrated that soluble urate is biologically active, with effects on renal and vascular function. Among its mechanisms of action, soluble urate inhibits synthesis of the potent vasodilator nitric oxide; induces smooth muscle cell proliferation by activating mitogen-activated protein kinases; and stimulates cyclooxygenase-2 and platelet-derived growth factor synthesis, all contributing to arterial vasoconstriction.^{213,214} Soluble urate has also been shown to directly stimulate the renin-angiotensin system in the kidney and to induce renal interstitial and tubular inflammation.^{215,216} As noted earlier (see Evolutionary Considerations), these effects may promote hypertension; other studies suggest that hyperuricemia may also contribute to the risk for both renal insufficiency and myocardial infarction, though additional research is necessary to better assess the direction of causality.²¹⁷ Several recent clinical trials suggest that lowering serum urate levels may reduce the risk of myocardial

infarction and slow the progression of renal failure.^{218,219} Hyperuricemia may also promote insulin resistance in adipose cells, potentially serving as a risk factor for diabetes and metabolic syndrome.^{220,221} Urate may also play a role and/or serve as a biomarker in osteoarthritis (OA).^{149,222} In contrast to the adverse effects of serum urate, accumulating evidence suggests that hyperuricemia may protect against neurologic diseases such as dementia, multiple sclerosis, and Parkinson's and Huntington's diseases.²²³⁻²²⁶ Recognition of uric acid's biologic complexity will likely lead to a better understanding of its impact on the immune, cardiovascular, endocrine, neurologic, and musculoskeletal systems.

Clinical Features and Treatment of Gout

CHRISTOPHER M. BURNS •
ROBERT L. WORTMANN

KEY POINTS

Hyperuricemia is defined as a serum urate level greater than 6.8 mg/dL.

Acute gout can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, corticosteroids, or adrenocorticotrophic hormone. The effectiveness of treatment depends more on how quickly the therapy is initiated than which agent is used.

Before starting a specific urate-lowering agent, the patient should be treated with low-dose colchicine or an NSAID in an attempt to prevent further attacks.

Regardless of whether a xanthine oxidase inhibitor, a uricosuric agent, or a uricase is used to treat hyperuricemia, the patient should receive the lowest dose that maintains the serum urate level below 6.8 mg/dL—preferably below 6 mg/dL.

In addition to allopurinol, febuxostat and pegloticase are now available as urate-lowering agents for the treatment of gout.

Individuals who are hyperuricemic should be screened for hypertension, coronary artery disease, diabetes, obesity, and alcoholism.

Using a specific urate-lowering agent to manage asymptomatic hyperuricemia is not recommended. However, associated conditions such as hypertension, coronary artery disease, diabetes, obesity, and alcoholism should be managed in these patients, as well as in those with symptomatic gout.

Gout has been called the “king of diseases” and the “disease of kings.” Today, the term *gout* is used to represent a heterogeneous group of diseases found exclusively in humans that include the following characteristics:

- Elevated serum urate concentration (hyperuricemia)
- Recurrent attacks of acute arthritis in which monosodium urate monohydrate crystals are demonstrable in synovial fluid leukocytes
- Aggregates of sodium urate monohydrate crystals (tophi) deposited chiefly in and around joints, which sometimes lead to deformity and crippling
- Renal disease involving glomerular, tubular, and interstitial tissues and blood vessels
- Uric acid nephrolithiasis

These manifestations can occur in various combinations.^{1,2}

Hyperuricemia denotes an elevated level of urate in the blood. This occurs in an absolute (or physiochemical) sense when the serum urate concentration exceeds the limit of solubility of monosodium urate in the serum, which is

6.8 mg/dL at 37° C. Thus a value greater than 6.8 mg/dL indicates supersaturation of body fluids. The serum urate concentration is elevated in a relative sense when it exceeds the upper limit of an arbitrary normal range, which is usually defined as the mean serum urate value plus two standard deviations in a sex- and age-matched healthy population. In most epidemiologic studies, the upper limit has been rounded off at 7 mg/dL in men and 6 mg/dL in women. A serum urate value in excess of 7 mg/dL begins to carry an increased risk of gouty arthritis or renal stones.

EPIDEMIOLOGY

KEY POINTS

Hyperuricemia is common and directly associated with serum creatinine, body mass index, age, blood pressure, and alcohol intake.

Serum urate levels are low in childhood and increase in men at puberty and in women at menopause.

The prevalence of gout ranges from 1% to 15% in populations with a clear increase in incidence in recent years, perhaps related to the assumption of a Western diet and the epidemic of obesity.

Hyperuricemia is fairly common, with prevalence ranging between 2.6% and 47.2% in various populations.^{3,4} A variety of factors appears to be associated with high serum urate concentrations. In adults, serum urate levels correlate strongly with the serum creatinine and urea nitrogen levels, body weight, height, age, blood pressure, and alcohol intake.⁵ In epidemiologic studies, body bulk (as estimated by body weight, surface area, or body mass index) has proved to be one of the most important predictors of hyperuricemia in people of many different races and cultures, with rare exceptions.⁶⁻⁸

Serum urate concentrations vary with age and sex. Children normally have a concentration in the range of 3 to 4 mg/dL because of high renal uric acid clearance.⁹ At puberty, serum urate concentrations increase by 1 to 2 mg/dL in males, and this higher level is generally sustained throughout life. In contrast, females exhibit little change in the serum urate concentration until menopause, when concentrations increase and approach those seen in adult men. The mechanism of lower serum urate levels in women is a consequence of sex hormones and is related to a higher fractional excretion of urate secondary to lower tubular urate postsecretory reabsorption.¹⁰

The incidence of gout varies among populations, with an overall prevalence ranging from less than 1% to 15.3%.⁵

This upper limit appears to be increasing.^{11,12} The prevalence increases substantially with age and with increasing serum urate concentration. The annual incidence rate of gout is 4.9% for urate levels greater than 9 mg/dL, 0.5% for values between 7 and 8.9 mg/dL, and 0.1% for values less than 7 mg/dL.¹³ For serum urate values greater than 9 mg/dL, the cumulative incidence of gout reaches 22% after 5 years.

ENVIRONMENTAL FACTORS

KEY POINTS

Many environmental factors are associated with gout including alcohol consumption, particularly beer, and diet.

Certain foods clearly promote hyperuricemia and gout including alcohol, seafood, and red meat.

The consumption of some foods may be protective, especially milk and yogurt.

An association between alcohol consumption and gout has been recognized for centuries. The risk of developing gout varies by the type of alcohol ingested.¹⁴ Beer, which is purine rich, carries the highest risk; this risk is substantially greater than that for liquor. Moderate wine drinking does not increase the risk of gout. The quantity of alcohol also strongly correlates with gout. Compared with men who did not consume alcohol, the relative risk of gout was 1.32 for an alcohol intake of 10 to 14.9 g/day, 1.49 for 15 to 29.9 g/day, 1.96 for 30 to 49.9 g/day, and 2.53 for 50 g/day and higher, with calculations based on 12.8 g of alcohol per 12 oz serving of regular beer, 11.3 g per 12 oz. serving of light beer, 11 g per 4 oz. serving of wine, and 14 g per shot of liquor.

Diet also influences hyperuricemia and gout. Serum urate levels increase with meat or seafood intake and decrease with dairy intake.¹⁵ Men in the highest quintile of seafood consumption have a 51% higher risk of developing gout, and those in the highest quintile of meat intake have a 41% higher risk. However, consumption of oatmeal and purine-rich vegetables (e.g., peas, mushrooms, lentils, spinach, cauliflower) is not associated with an increased risk for gout. The consumption of milk one or more times a day or yogurt consumption at least once every other day is associated with lower serum urate levels.

GENETICS

KEY POINTS

Rare forms of early hyperuricemia and gout have a clear genetic and metabolic basis.

Gout often runs in families, probably because of inherited factors affecting serum urate levels through renal urate clearance.

Recent genome-wide association studies have identified polymorphisms in several candidate genes encoding urate transporters in the renal proximal tubules as determinants of serum urate levels and the risk of gout.

Since antiquity, gout has been recognized as a familial disorder. The familial incidences reported range from 11% to 80%.¹⁶ In two large series, one English and one American, about 40% of gouty subjects gave a positive family history of gout. These wide discrepancies may be attributed in part to variations in diligence and pursuit of genealogic data. When all available data are considered, they suggest that serum urate concentrations are controlled by polygenic traits. Several rare forms of hyperuricemia and gout such as hypoxanthine phosphoribosyltransferase deficiency, phosphoribosyl-1-pyrophosphate synthetase overactivity, and familial hyperuricemia nephropathy have a clear genetic basis, most presenting in childhood or early adulthood¹⁷ (see later).

But the vast majority of gout patients do not have one of these discrete inborn errors of metabolism as explanations for their disease. In most gout patients, the mechanism of hyperuricemia is simply inefficient renal excretion of uric acid.^{18,19} It stands to reason then that some of the familial predisposition to gout is related to inherited variations in renal urate handling. With the recent advances in our understanding of the transport of uric acid in the renal proximal tubule, some of this variability is being clarified. Genome-wide association studies (GWASs) have identified genetic variations of the *SLC2A9/GLUT9* and *ABCG2* genes as important determinants of serum urate levels (see Chapter 94).²⁰ Curiously, the data for the role of polymorphisms in *URAT1 (SLC22A12)*, a key urate transporter involved in renal proximal tubule urate reabsorption, are thus far inconsistent.²¹⁻²⁵ Glucose transporter 9 (*GLUT9, SLC2A9*) is an electrogenic hexose transporter whose splicing variants mediate reabsorption of uric acid, along with glucose and fructose, at the renal proximal tubule epithelial cell, first at the apical membrane, then through the basolateral membrane, and on into the circulation.²⁶⁻²⁹ Polymorphisms in *SLC2A9* are associated with a lower serum uric acid, with stronger effects seen in women, possibly accounting for 0.5% to 2% of the variance in serum urate concentration in men and 3.4% to 8.8% in women.^{22,27,30-32} In five of six populations studied by GWAS, *SLC2A9* polymorphisms were associated with a decreased incidence of self-reported gout, particularly in women.^{27,30,31} Indeed, three patients with renal hypouricemia have been identified with loss-of-function mutations in *SLC2A9*.^{28,33} The implication is that certain polymorphisms in *SLC2A9* enhance renal uric acid excretion, lower serum urate levels, and are therefore protective against gout, particularly in women.

A gene product of *ABCG2*, human adenosine triphosphate (ATP)-binding cassette, subfamily G, 2, appears to be a secretory urate transporter located in the renal proximal tubule apical border.³⁴ Polymorphisms in *ABCG2* are associated with a higher serum urate concentration in humans, with a more potent influence in men, potentially accounting for 1.6% to 2.1% of the variance in serum urate concentration in men and 0.5% to 0.8% in women.^{23,31} One *ABCG2* polymorphism, rs2231142, has been associated with a higher incidence of gout only in males (odds ratio [OR], 2.03 for self-reported gout).³¹ In a transfection model in *Xenopus* oocytes, the common mutation in human *ABCG2* encoded by rs2231142, Q141K, resulted in a 53% decrease in urate transport compared with the wild-type

gene product.³⁴ The implication is that certain polymorphisms in *ABCG2* result in reduced proximal tubule urate secretion, increased serum urate concentrations, and a higher incidence of gout, at least in men.

Because the impact of comorbidities and environmental influences such as diet and lifestyle is so significant in gout, it remains to be seen whether risk contribution from genetic variation is clinically relevant, either directly or due to an unexpected interaction with these other factors. An example of the latter is the potential influence the urate-fructose/glucose exchange transporter *SCL2A9* polymorphisms may have on the well-described association of heavy consumption of soft drinks with elevated serum urate levels and gout.³⁵⁻³⁸

CLINICAL FEATURES

KEY POINTS

The three stages of gout are asymptomatic hyperuricemia, acute and intercritical gout, and chronic gouty arthritis.

A period of asymptomatic hyperuricemia lasts up to 20 years before the initial attack of gout or nephrolithiasis.

The first gout attack generally occurs at age 40 to 60 in men and after age 60 in women.

Many drugs raise serum urate levels and predispose to gout attacks, especially diuretics.

Most attacks of gout, especially early in the course, are monoarticular, with a predilection for the first metatarsophalangeal joint (podagra) and have a characteristic abrupt and painful onset.

The differential diagnosis for acute gout is usually infectious arthritis or other crystal-induced synovitis, particularly pseudogout.

Ultrasonography appears to be a useful adjunct in the diagnosis of acute and chronic gout.

In untreated or undertreated individuals, chronic gout is characterized by the development of tophi and progressive joint damage.

Throughout its natural history, gout passes through three stages: (1) asymptomatic hyperuricemia, (2) episodes of acute gouty arthritis separated by asymptomatic intervals (termed *intercritical* or *interval gout*), and (3) chronic gouty arthritis, the period when tophi often become apparent.

The basic pattern of clinical gout begins with acute attacks of intensely painful arthritis. The first attack is usually monoarticular and associated with few constitutional symptoms. Later, attacks may become polyarticular and are associated with fever. Attacks vary in duration but are time limited. Over time, attacks recur at shorter intervals, last longer, and eventually resolve incompletely. This leads to the development of chronic arthritis that slowly progresses to a crippling disease on which acute exacerbations are superimposed.

Asymptomatic Hyperuricemia

Asymptomatic hyperuricemia is a condition in which the serum urate level is high, but gout—manifested by arthritis or uric acid nephrolithiasis—has not yet occurred. Most people with hyperuricemia remain asymptomatic throughout their lifetimes. The tendency toward acute gout increases with the serum urate concentration. The risk of nephrolithiasis increases with the serum urate level and with the magnitude of urinary uric acid excretion. The phase of asymptomatic hyperuricemia ends with the first attack of gouty arthritis or urolithiasis. In most instances, this occurs after at least 20 years of sustained hyperuricemia. Between 10% and 40% of gouty subjects have one or more attacks of renal colic before the first articular event.

Acute Gouty Arthritis

The first attack of acute gouty arthritis usually occurs between age 40 and 60 years in men and after age 60 in women. Onset before age 25 should raise the possibility of an unusual form of gout, perhaps one related to a specific enzymatic defect that causes marked purine overproduction, an inherited renal disorder, or the use of cyclosporine.

A single joint is involved in about 85% to 90% of first attacks, with the first metatarsophalangeal joint being the most commonly affected site. The initial attack is polyarticular in 3% to 14%. Acute gout is predominantly a disease of the lower extremities, but eventually, any joint of any extremity may be involved. Ninety percent of patients experience acute attacks in the great toe at some time during the course of their disease. Next in order of frequency are the insteps, ankles, heels, knees, wrists, fingers, and elbows. Acute attacks rarely affect the shoulders, hips, spine, sacroiliac joints, sternoclavicular joints, acromioclavicular joints, or temporomandibular joints.^{39,40} Acute gouty bursitis, tendinitis, or tenosynovitis can also occur.^{41,42} Urate deposition and subsequent gout appear to have a predilection for previously damaged joints such as in Heberden's nodes of older women.⁴³ The differential diagnosis is usually septic arthritis or other crystal-induced arthritis, but a broader differential should be considered in confusing cases (Table 95-1).

Some patients report a history of short, trivial episodes of "ankle sprains," sore heels, or twinges of pain in the great toe before the first dramatic gouty attack. In most patients, however, the initial attack occurs with explosive suddenness and commonly begins at night after the individual has gone to sleep feeling well. Within a few hours of onset, the affected part becomes hot, dusky red, swollen, and extremely tender. Occasionally, lymphangitis may develop. Systemic signs of inflammation may include leukocytosis, fever, and elevation of the erythrocyte sedimentation rate. Radiographs usually show only soft tissue swelling during early episodes.

The course of untreated acute gout is highly variable. Mild attacks may subside in several hours or persist for only a day or two and never reach the intensity described for the classic attack. Severe attacks may last days to weeks. The skin over the joint often desquamates as the erythema subsides. With resolution, the patient becomes asymptomatic and enters the intercritical period.

Table 95-1 Differential Diagnosis of Gout

Acute Gouty Arthritis
Other crystal arthritis, especially CPPD, or pseudogout, but also basic calcium phosphate (hydroxyapatite) and others
Septic arthritis including gonorrhea
Trauma
Cellulitis
Lyme arthritis
Reactive arthritis
Psoriatic arthritis
Sarcoidosis
Unusual presentations of other inflammatory arthritides including rheumatoid arthritis
Chronic Gouty Arthritis
Rheumatoid or other chronic inflammatory arthritis
CPPD
(Inflammatory) osteoarthritis
Lyme disease
Indolent infections including mycobacterial

CPPD, calcium pyrophosphate disease.

Drugs may precipitate acute gout by either increasing or decreasing serum urate levels acutely. The occurrence of gout after the initiation of antihyperuricemic therapy is well established. In fact, the more potent the urate-lowering effect, the more likely there is to be an acute attack.⁴⁴ Drug-induced gout secondary to increased serum urate levels occurs on occasion with diuretic therapy, intravenous heparin, and cyclosporine.⁴⁵⁻⁴⁷ Diuretic therapy in the elderly appears to be a particularly important precipitating factor for gouty arthritis. Other provocative factors include trauma, alcohol ingestion, surgery, dietary excess, hemorrhage, foreign protein therapy, infections, and radiographic contrast exposure.^{48,49} The risk of a patient with gout developing an attack during hospitalization is 20%.⁵⁰

The definitive diagnosis of gout is best established by aspiration of the joint and identification of intracellular needle-shaped crystals that have negative birefringence with compensated polarized light microscopy. However, various alternatives have been proposed for a presumptive diagnosis. These include the triad of acute monoarticular arthritis, hyperuricemia, and a dramatic response to colchicine therapy,⁵¹ a set of criteria proposed by the American College of Rheumatology (Table 95-2) in 1977,⁵² and 10 “propositions” for diagnosis by a European League Against Rheumatism (EULAR) panel of experts in 2006 (Table 95-3).⁵³ There are limitations to using any of these schemes. First, although the diagnosis of acute gouty arthritis can be strongly suggested by the typical presentation, not all inflammation of the great toe (podagra) in hyperuricemic patients is caused by gout.⁵⁴ Second, some patients with gout are normouricemic at the time of an acute attack, a phenomenon related to alcohol use or a consequence of interleukin (IL)-6 generation by the acute inflammatory process.⁵⁵⁻⁵⁷ Third, diseases other than gout can occasionally improve with colchicine therapy; these include pseudogout, hydroxyapatite calcific tendinitis, sarcoid arthritis, erythema nodosum, serum sickness, rheumatoid arthritis, and familial Mediterranean fever.¹⁶ Finally, the simultaneous presence of both gout and septic arthritis can be confusing clinically, with the former masking the latter.⁵⁸

The use of ultrasonography as a means of diagnosing acute and chronic gout is gaining favor. The characteristic finding is a superficial, hyperechoic, irregular band on the surface of articular cartilage, the so-called “double contour sign” or “urate icing,” in one study seen in 92% of gouty joints and in no joints of patients with other types of arthritis.^{59,60} Also characteristic is nonhomogeneous tophaceous material surrounded by an anechoic rim. Further support for ultrasound comes from the demonstration of resolution of these findings in a small number of gout patients on urate-lowering therapy who maintained a serum urate less than or equal to 6 mg/dL for at least 7 months.⁶¹ Recent studies presented in abstract form have indicated excellent concordance between ultrasound readers in identifying changes, the presence of these findings even in those with asymptomatic hyperuricemia, and the superiority of ultrasound over conventional radiography in detecting gouty erosions.⁶²⁻⁶⁴ Ultrasound now appears to be a technology that will be an important ancillary approach to the diagnosis and treatment of gout. Magnetic resonance imaging is much more sensitive than even ultrasound at detecting gouty erosions in patients with gout and normal plain radiographs.⁶⁵⁻⁶⁷ Computed tomography (CT) scan is also sensitive for the detection of erosions and tophi, and three-dimensional CT may have utility in the quantitation of the size of tophi during clinical trials in gout.⁶⁷

Intercritical Gout

The terms *intercritical gout* and *interval gout* have been applied to the periods between gouty attacks. Some patients never have a second attack. However, most patients suffer a second attack within 6 months to 2 years. In Gutman's series,⁶⁸ 62% had recurrences within the first year, 16% in 1 to 2 years, 11% in 2 to 5 years, and 4% in 5 to 10 years; 7% had experienced no recurrence in 10 or more years. The frequency of gout attacks usually increases over time in untreated patients. Later attacks have a less explosive onset, are polyarticular, become more severe, last longer, and abate more slowly. Nevertheless, recovery is complete.

Table 95-2 Criteria for the Classification of Acute Gouty Arthritis

The presence of characteristic urate crystals in the joint fluid, or a tophus proved to contain urate crystals by chemical means or polarized light microscopy, or the presence of 6 of the following 12 clinical, laboratory, and radiographic phenomena:
More than 1 attack of acute arthritis
Maximal inflammation developed within 1 day
Attack of monoarticular arthritis
Joint redness observed
First metatarsophalangeal joint painful or swollen
Unilateral attack involving first metatarsophalangeal joint
Unilateral attack involving tarsal joint
Suspected tophus
Hyperuricemia
Asymmetric swelling within a joint (radiograph)
Subcortical cysts without erosions (radiograph)
Negative culture of joint fluid for microorganisms during attack of joint inflammation

Adapted from Wallace SL, Robinson H, Masi AT, et al: Preliminary criteria for the classification of acute arthritis of primary gout, *Arthritis Rheum* 20:895-900, 1977.

Table 95-3 Propositions and Strength of Recommendation (SOR): Order According to Topic (Clinical, Urate Crystals, Biochemical, Radiographic, and Risk Factors/Comorbidities)

	Proposition	SOR (95% CI) VAS 100	A-B%*
1	In acute attacks the rapid development of severe pain, swelling, and tenderness that reaches its maximum within just 6-12 hr, especially with overlying erythema, is highly suggestive of crystal inflammation though not specific for gout	88 (80-96)	93
2	For typical presentations of gout (such as recurrent podagra with hyperuricemia), a clinical diagnosis alone is reasonably accurate but not definitive without crystal confirmation	95 (91-98)	100
3	Demonstration of MSU crystals in synovial fluid or tophus aspirates permits a definitive diagnosis of gout	96 (93-100)	100
4	A routine search for MSU crystals is recommended in all synovial fluid samples obtained from undiagnosed inflamed joints	90 (83-97)	87
5	Identification of MSU crystals from asymptomatic joints may allow definite diagnosis in intercritical periods	84 (78-91)	93
6	Gout and sepsis may coexist, so when septic arthritis is suspected, Gram stain and culture of synovial fluid should still be performed even if MSU crystals are identified	93 (87-99)	93
7	Although being the most important risk factor for gout, serum uric acid levels do not confirm or exclude gout because many people with hyperuricemia do not develop gout, and during acute attacks serum levels may be normal	95 (92-99)	93
8	Renal uric acid excretion should be determined in selected gout patients, especially those with a family history of young-onset gout, onset of gout under age 25, or with renal calculi	72 (62-81)	60
9	Although radiographs may be useful for differential diagnosis and may show typical features in chronic gout, they are not useful in confirming the diagnosis of early or acute gout	86 (79-94)	93
10	Risk factors for gout and associated comorbidity should be assessed including features of the metabolic syndrome (obesity, hyperglycemia, hyperlipidemia, hypertension)	93 (88-98)	100

*A-B%: percentage of strongly to fully recommended, based on the EULAR ordinal scale (A = fully recommended, B = strongly recommended, C = moderately recommended, D = weakly recommended, E = not recommended).

CI, confidence interval; MSU, monosodium urate; VAS, visual analogue scale (0-100 mm, 0 = not recommended at all, 100 = fully recommended).

From Zhang W, Doherty M, Pascual E, et al: EULAR evidence based recommendations for gout. Part I: diagnosis. Report of a task force of the standing committee for international clinical studies including therapeutics (ESCIIT), *Ann Rheum Dis* 65:1301, 2006.

Radiographic changes may develop during the intercritical period despite no sign of tophi on physical examination. These changes are more likely in patients with more severe hyperuricemia and more frequent acute attacks.^{50,69}

The diagnosis of gout in a hyperuricemic patient with a history of acute attacks of monoarthritis may be difficult or inconclusive during the intercritical phase. Aspiration of an asymptomatic joint, however, can be a useful adjunct in the diagnosis of gout if urate crystals are demonstrated. Joint fluids obtained from gouty patients during the intercritical phase revealed monosodium urate crystals in 12.5% to 90% of joints.⁷⁰ Such crystals in asymptomatic joints are often associated with mild synovial fluid leukocytosis, which suggests the potential to contribute to joint damage even in the intervals between attacks.

Chronic Gouty Arthritis

Eventually, the patient may enter a phase of chronic polyarticular gout with no pain-free intercritical periods. At this stage, gout may be easily confused with other types of arthritis or other conditions.⁷¹⁻⁷³ The time from the initial attack to the beginning of chronic symptoms or visible tophaceous involvement is highly variable in studies of untreated patients. Hensch reported intervals ranging from 3 to 42 years, with an average of 11.6 years between the first attack and the development of chronic arthritis.⁷⁴ Ten years after the first attack, about half the individuals were still free of obvious tophi and most of the remainder had only minimal deposits. Thereafter, the proportion of those with nontophaceous involvement slowly declined, to 28% after 20 years. Two percent of the patients had severe crippling disease some 20 years after the initial attack.

The rate of formation of tophaceous deposits correlates with both the degree and the duration of hyperuricemia. The principal determinant is the serum urate level.⁵⁰ Gutman⁷⁵ found the mean serum urate concentration to be 9.1 mg/dL in 722 patients without tophi, 10 to 12 mg/dL in 456 patients with minimal to moderate tophi, and greater than 11 mg/dL in 11 patients with extensive tophaceous involvement. The rate of tophus formation also increases with the severity of renal disease and the use of diuretics.⁴⁵

Tophaceous gout is the consequence of the chronic inability to eliminate urate as rapidly as it is produced. As the urate pool expands, deposits of urate crystals appear in cartilage, synovial membranes, tendons, soft tissues, and elsewhere. Tophi are rarely present at the time of an initial attack of primary gout^{76,77}; they are more likely to be present in gout secondary to myeloproliferative diseases, in juvenile gout-complicating glycogen storage diseases (GSDs), in Lesch-Nyhan syndrome, or after allograft transplantation in patients treated with cyclosporine.^{16,78}

Tophi can occur in a variety of locations. Tophaceous deposits may produce irregular, asymmetric, moderately discrete tumescence of the fingers (Figure 95-1), hands, knees, or feet. Tophi also form along the ulnar surfaces of the forearm, as saccular distentions of the olecranon bursa (Figure 95-2), in the antihelix of the ear (Figure 95-3), or as fusiform enlargements of the Achilles tendon (Figure 95-4). The process of tophaceous deposition advances insidiously. Although the tophi themselves are relatively painless, acute inflammation can occur around them. Eventually, extensive destruction of the joints and large subcutaneous tophi may lead to grotesque deformities, particularly of the hands and feet, and to progressive crippling (Figure 95-5).

Figure 95-1 Tophus of the fifth digit, with a smaller tophus over the fourth proximal interphalangeal joint.

Figure 95-3 Tophus of the helix of the ear adjacent to the auricular tubercle.

Figure 95-2 Saccular tophaceous enlargements of the olecranon bursae, with small cutaneous deposits of urate.

Figure 95-4 Tophi of Achilles tendons and their insertions in a patient with gout.

Figure 95-5 A and B, Radiographs demonstrating severe destructive changes in tophaceous gout.

Figure 95-6 Radiographs show changes typical of bony tophi including soft tissue distortion, erosions with sclerotic margins, and overwhelming edges. Joint space narrowing is minimal, despite the large erosions. (From Nakayama DA, Barthelemy C, Carrera G, et al: *Tophaceous gout: a clinical and radiographic assessment*, *Arthritis Rheum* 27:468, 1984.)

The tense, shiny, thin skin overlying the tophus may ulcerate and extrude white, chalky, or pasty material composed of urate crystals. Secondary infection of tophi is rare.

Typical radiographic changes, particularly erosions with sclerotic margins and overhanging edges of bone, occur with the development of tophi (Figure 95-6).⁷⁹ These may be difficult to distinguish from erosions of other causes, but the presence of a thin, overhanging calcified edge is strong evidence of gout. Calcifications can be seen in some tophi, and bony ankylosis may rarely occur. Ultrasonography, magnetic resonance imaging, and computed tomography can demonstrate tophi, with the last providing the most specific images.^{59-68,80}

Tophi can produce a marked limitation of joint movement by involvement of the joint structure directly or of a tendon serving the joint. Any joint can be involved, although those of the lower extremity are affected primarily. Spinal joints do not escape urate deposition,^{73,81} but acute gouty spondylitis is unusual. Symptoms related to nerve or spinal cord compression by tophi have rarely been observed. Tophi rarely occur in myocardium, valves, cardiac conduction system, various parts of the eye, and larynx.^{82,83}

ASSOCIATED CONDITIONS

KEY POINTS

Gout is associated with obesity, hypertriglyceridemia, glucose intolerance and the metabolic syndrome, hypertension, atherosclerosis, and hypothyroidism.

Renal insufficiency is frequently associated with hyperuricemia and gout.

Hyperuricemia is a common cause of nephrolithiasis, and rarely, chronic hyperuricemia may cause urate nephropathy and acute hyperuricemia may lead to uric acid nephropathy in the tumor lysis syndrome.

Alcohol use, lead intoxication, and cyclosporine treatment are associated with hyperuricemia and gout.

A diagnosis of gout should prompt a search for the coexistence of these associated conditions.

The association of gout with obesity and overeating is well recognized.⁸⁴ In 6000 subjects, hyperuricemia was found in only 3.4% of those with a relative weight at or below the 20th percentile, in 5.7% of those between the 21st and 79th percentiles, and in 11.4% of those at or above the 80th percentile.⁸⁵

Hypertriglyceridemia has been reported in 75% to 80% of patients with gout,⁸⁶ and hyperuricemia is found in more than 80% of patients with hypertriglyceridemia.¹⁶ However, studies have been unable to show a correlation between serum urate and cholesterol values or a unique lipid phenotype.⁸⁷ Gouty patients who drink alcohol excessively have mean serum triglyceride levels that are higher than those of their obesity-matched controls and of non-alcohol-drinking gouty patients.⁸⁸

Hyperuricemia has been reported in 2% to 50% of patients with diabetes mellitus, and gouty arthritis has been reported in less than 0.1% to 9%.⁸⁹ Abnormal glucose tolerance tests have been noted in 7% to 74% of patients with gout, depending, in part, on the criteria used.⁹⁰

Hyperuricemia has been reported in 22% to 38% of patients with untreated hypertension. This figure increases to 67% when diuretic therapy and renal disease are present.¹⁶ Hyperuricemia may be an indication of a potential risk for hypertension in adolescent males.⁹¹ Hypertension is present in one-fourth to one-half of patients with classic gout, but the presence of hypertension is unrelated to the duration of gout.^{84,85} Elevated serum urate concentrations are associated with increased tubular reabsorption of sodium.⁹⁰ The serum urate concentration also correlates inversely with renal blood flow and urate clearance and correlates directly with both renovascular and total resistance. Therefore the association between hypertension and hyperuricemia may be related to the reduction of renal blood flow in hypertension. In addition, uric acid causes smooth muscle proliferation in vitro and vascular disease in animal models through a mechanism that involves complex intracellular signaling, mitogen-activated protein kinase activation, and platelet-derived growth factor expression.^{92,93}

The association between hyperuricemia and the manifestations of atherosclerosis has led to speculation that hyperuricemia is a risk factor for coronary artery disease. Some studies show no clear associations among blood pressure, blood glucose, or serum cholesterol and serum urate concentration when adjustments are made for the effects of age, sex, and relative weight^{85,94-97}; the serum urate concentrations of persons with coronary heart disease are not significantly different from the mean levels of the population.^{97,98} Other studies, however, maintain that hyperuricemia is an independent risk factor for coronary artery disease.^{99,100}

The term *metabolic syndrome* has been applied to a cluster of abnormalities including resistance to insulin-stimulated glucose uptake, hyperinsulinemia, hypertension, and dyslipoproteinemia that are characterized by high levels of plasma triglycerides and high-density lipoprotein cholesterol. Hyperuricemia closely correlates with the degree of insulin resistance⁹⁷⁻¹⁰³ and therefore is a likely feature of metabolic syndrome. Metabolic syndrome has been associated with coronary artery disease, and hyperuricemia as a component of metabolic syndrome may explain the previously recognized association between coronary artery disease and hyperuricemia. A recent study concluded that the relationship between hyperuricemia and acute myocardial infarction is independent, but patients who experience gouty arthritis are at an increased risk for myocardial infarction. This association could not be explained by renal function, metabolic syndrome, diuretic use, or traditional cardiovascular risk factors.¹⁰⁴

Alcohol consumption has long been associated with hyperuricemia and gout. In susceptible persons, alcohol use can precipitate acute gouty arthritis. An epidemiologic study in Saudi Arabia, where alcohol consumption is rare, revealed an 8.42% prevalence of hyperuricemia but no cases of gout among the study group.¹⁰⁵ Both a decrease in the renal excretion of uric acid and an increase in uric acid production seem to be important factors in this association.¹⁰⁶ Ethanol increases uric acid production by accelerating the turnover of ATP. Among alcoholic beverages, beer may have more potent effects on uric acid production because of its high guanosine content.¹⁴

There appears to be a significant increased prevalence of hypothyroidism among both female and male patients with gouty arthritis.¹⁰⁷ Hyperuricemia may also be more prevalent in patients with hypothyroidism. Thyroid replacement therapy is associated with a decrease in serum urate concentration caused by an increased uric acid diuresis—a change not explained solely by a change in creatinine clearance.¹⁰⁸ Although the cause of hyperuricemia and gout in patients with hypothyroidism is unknown, it is speculated that urate metabolism is mediated by thyroid-stimulating hormone receptors in extrathyroidal tissues including the kidney and that these modulate urate homeostasis.

Studies of acutely ill patients in intensive care units indicate that markedly increased serum urate concentrations, in the vicinity of 20 mg/dL, are associated with hypotensive events and a poor prognosis.¹⁰⁹ This finding may be related to two factors. First, ischemic tissue may foster the degradation of ATP to purine end products, thereby enhancing the production of urate. The finding of

increased plasma ATP degradation products associated with hyperuricemia and adult respiratory distress syndrome supports this possibility.¹¹⁰ Second, the conversion of hypoxanthine to uric acid by xanthine oxidase during ischemia produces oxidant radicals, which are themselves associated with tissue injury.¹¹¹ It is possible that inhibition of xanthine oxidase with allopurinol may be a useful therapy in this setting.

Maternal serum urate concentrations normally decrease during pregnancy until the 24th week and then increase until 12 weeks after delivery.¹¹² An increase in the serum urate level occurs in preeclampsia and toxemia of pregnancy, owing to a decrease in the renal clearance of urate.¹¹³ Perinatal mortality is markedly increased when maternal plasma urate levels are raised, usually in association with early-onset preeclampsia. The highest mortality rate is seen with serum urate concentrations higher than 6 mg/dL and diastolic blood pressures greater than 110 mm Hg. Labor itself is associated with an increased serum urate level, and it remains elevated for 1 to 2 days after delivery.

Gout is rarely seen in patients with rheumatoid arthritis, systemic lupus erythematosus, or ankylosing spondylitis.^{41,114-116} The basis for the decreased concurrence of these disorders is unclear, although the long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs) or corticosteroids may mask the clinical features of gout in some of these patients.

Renal Disease

After gouty arthritis, renal problems appear to be the most frequent complication of hyperuricemia. Twenty percent to 40% of patients with gout have albuminuria, which is usually mild and often intermittent. Hyperuricemia alone may be implicated as the cause of chronic kidney disease only when the concentration of urate chronically exceeds 13 mg/dL in men or 10 mg/dL in women.¹¹⁷ Before the routine treatment of asymptomatic hypertension, renal failure accounted for 10% of the deaths in patients with gout. Whether moderate hyperuricemia has a direct harmful effect on renal function is unclear. Some evidence suggests that urate damages the kidneys and leads to hypertension.^{92,93}

The term *urate nephropathy* is used to describe the deposition of urate crystals in the interstitium of the medulla and pyramids, with a surrounding giant cell reaction—a distinctive histologic finding characteristic of the gouty kidney (Figure 95-7). Factors such as coexistent hypertension, chronic lead exposure, ischemic heart disease, and primary pre-existing renal insufficiency probably play important roles in the pathogenesis of this pathology. Although urate nephropathy appears to exist as a distinct entity, it is not believed to be an important contributor to renal function in most gouty patients.^{16,118}

In contrast, *uric acid nephropathy* is the term used to describe acute renal failure resulting from the precipitation of large quantities of uric acid crystals in the collecting ducts and ureters. This complication most commonly occurs in patients with leukemia and lymphoma as a result of rapid malignant cell turnover, often during chemotherapy.^{119,120} This syndrome (also termed *acute tumor lysis syndrome*) has

Figure 95-7 **A**, Urate deposit in the medulla of the kidneys as seen in an alcohol-fixed section stained with hematoxylin and eosin ($\times 250$). **B**, Adjacent section of the deposit shown in **A**, stained with methenamine silver ($\times 250$). **C**, Adjacent section of the deposit shown in **A** seen with polarized light ($\times 250$).

been more clearly defined as hyperuricemia, lactic acidosis, hyperkalemia, hyperphosphatemia, and hypocalcemia and is most commonly observed in patients with aggressive, rapidly proliferating tumors including lymphoproliferative disorders and metastatic medulloblastoma. Uric acid nephropathy is less commonly found with other neoplasms, after epileptic seizures, after vigorous exercise with heat stress, and after angiography and coronary artery bypass surgery.¹⁶

In the tumor lysis syndrome, the large amount of nucleic acid in nucleotides liberated with massive cytolysis is converted rapidly to uric acid. Typically, there is marked hyperuricemia, with a mean serum urate level of 20 mg/dL (range, 12 to 80 mg/dL). The pathogenesis of acute renal failure in uric acid nephropathy is related to the precipitation of uric acid in the distal tubules and collecting ducts, the sites of maximal acidification and concentration of urine. Oliguria, or even anuria, and azotemia may occur. There may be “gravel” or “sand” noted in the urine. The ratio of urinary uric acid to creatinine in these patients typically exceeds 1; in patients with most other causes of acute renal failure, the ratio is 0.4 ± 0.3 .¹²⁰

Nephrolithiasis occurs in 10% to 25% of patients with primary gout, a prevalence greater than that in the general population. The likelihood of stones in a given patient with gout increases with the serum urate concentration and with amounts of urinary uric acid excretion.^{121,122} It exceeds 50% with a serum urate value above 13 mg/dL or with urinary uric acid excretion rates in excess of 1100 mg every 24 hours.

Uric acid calculi account for approximately 10% of all stones in patients in the United States; elsewhere, rates range from as low as 5% up to 40% in Israel and Australia, respectively.¹⁶ Uric acid stones can occur in patients with no history of gouty arthritis, and only 20% in this group are hyperuricemic. Other renal stone disease is associated with

hyperuricemia and gout. Gouty subjects also have an increased incidence of stones that contain calcium. In addition, about 30% of patients with recurrent calcium stone disease have either an increased urinary uric acid excretion rate or hyperuricemia. A causative link between uric acid and recurrent calcium oxalate stones is provided by reports of reduced stone frequency in patients treated with allopurinol.

Finally, the report of uric acid as the major constituent of a stone obtained from a patient with no apparent abnormalities of uric acid metabolism should suggest the possibility that the constituent is actually 2,8-dihydroxyadenine and that the patient has adenine phosphoribosyltransferase deficiency.¹²³ This is because x-ray diffraction is required to distinguish uric acid from 2,8-dihydroxyadenine.

Familial juvenile hyperuricemic nephropathy (FJHN), sometimes called *familial juvenile gouty nephropathy*, was first described in 1960.¹²⁴ This disorder is inherited as an autosomal dominant trait with a high degree of penetrance and is usually associated with gout. Renal disease typically develops in the second decade of life and progresses to end-stage renal failure by midlife.¹²⁵⁻¹²⁷ Histologic examination of kidney tissue reveals tubulointerstitial inflammation and splitting of thickened tubular basement membranes. The primary diagnostic criterion is a reduced fractional excretion of urate (defined as uric acid clearance factored by creatinine clearance $\times 100$ equal to 5% or less; normal is 8% to 18%).¹²⁸ The dramatically low fractional excretion of urate and the early onset of disease are conspicuous characteristics of FJHN and distinguish it from other autosomal dominant hyperuricemic disorders that usually appear later in life (Table 95-4). Genotype mapping has linked the gene for FJHN to chromosome 16p12-p11.¹²⁶

Autosomal dominant medullary cystic kidney disease (ADMCKD) is another hereditary nephropathy that usually includes gout among its constellation of symptoms. The

Table 95-4 Genetics of Renal Diseases Associated with Gout

Condition	Inheritance	Chromosomal Location	Gene
FJHN	AD	16p12.3 17cenq21.3	Uromodulin Hepatic nuclear factor 1 β
MCKD type 1	AD	1q21	?
MCKD type 2	AD, AR	16p12.3	Uromodulin

AD, autosomal dominant; AR, autosomal recessive; FJHN, familial juvenile hyperuricemic nephropathy; MCKD, medullary cystic kidney disease.

onset of renal dysfunction occurs later than in those with FJHN. Renal histology reveals numerous corticomedullary and intramedullary cysts in the kidneys and increased medullary connective tissue. At least two loci appear to be responsible for ADMCKD. One, termed ADMCKD1, is located on chromosome 1; the other, ADMCKD2, is a 16p locus. ADMCKD2 and FJHN loci map to approximately the same region of chromosome 16p.¹²⁹

The chromosome 16p12 locus that harbors the candidate interval for FJHN and ADMCKD2 contains six candidate genes, including the uromodulin gene (*UMOD*).¹³⁰⁻¹³² *UMOD* encodes the Tamm-Horsfall protein, a glycosylphosphatidylinositol-anchored glycoprotein localized to the thick ascending limb of the loop of Henle. Amorphous deposits of uromodulin are present in the renal interstitium of patients with medullary cystic kidney disease.¹³³ Four different mutations in exon 4 have been identified in the *UMOD* gene. Because mutations in the same gene are responsible for both FJHN and ADMCKD, the two entities appear to be allelic variants in *UMOD* that cause decreased urinary concentrations of Tamm-Horsfall protein, with resulting hyperuricemia and progressive renal failure.¹³⁴

Lead Intoxication

Hyperuricemia and gout are well-recognized complications of chronic lead intoxication, with the prevalence of gout in patients with plumbism ranging between 6% and 50%.¹³⁵ Although a renal defect is recognized, it has not been well defined.^{136,137} Some patients with primary gout have increased blood lead levels compared with age- and sex-matched controls, despite the absence of a history of overt lead exposure.¹³⁸ This suggests that occult chronic lead intoxication may play a causative role in some cases of primary gout (up to 36% of some gout populations).¹³⁵ In addition, patients with gout who have renal impairment seem to have an increased quantity of mobilized lead compared with gouty patients with normal renal function.¹³⁹ These observations suggest an important role for lead in the pathogenesis of gouty nephropathy.

Cyclosporine-Induced Hyperuricemia and Gout

Cyclosporine interferes with the renal excretion of uric acid. Hyperuricemia and gout occur with increased frequency among transplant recipients treated with cyclosporine and are even more common when diuretics are used concomitantly.^{78,140} However, serum urate levels do not correlate directly with cyclosporine levels or with the degree of hypertension or renal insufficiency. The onset of gout may occur soon after transplantation, with a mean of about 17 months. Gouty attacks may be typical and monoarticular, or they may affect unusual sites such as the shoulder, hip, or sacroiliac joints. Polyarticular attacks and an accelerated course, with early development of tophi, may also be observed. Nephrolithiasis develops in about 3% of renal transplant patients. All calculi from azathioprine-treated patients are composed of calcium compounds, whereas 60% of the calculi from those treated with cyclosporine contain uric acid.¹⁴¹

CLASSIFICATION OF HYPERURICEMIA AND GOUT

KEY POINTS

Primary hyperuricemia and gout are caused by decreased renal uric acid excretion in more than 90% and overproduction of urate in less than 10% of affected patients.

Secondary hyperuricemia and gout are usually related to decreased renal urate clearance as a direct or indirect consequence of the primary disease process.

Four known specific inborn errors of purine metabolism with overproduction of urate account for less than 1% of cases of secondary hyperuricemia and gout.

The concentration of urate in body fluids is determined by the balance between production and elimination. Accordingly, hyperuricemia may be caused by an excessive rate of urate production, a decrease in the renal excretion of uric acid, or a combination of both events.

Hyperuricemia and gout may be classified as follows (Table 95-5):

Primary: These cases appear to be innate, neither secondary to an acquired disorder nor the result of a subordinate manifestation of an inborn error that leads initially to a major disease unlike gout. Some cases of primary gout have a genetic basis; others do not.

Secondary: These cases develop in the course of another disease or as a consequence of drug use.

Idiopathic: In these cases, a more precise classification cannot be assigned.

Further subdivisions within each major category are based on the identification of overproduction, underexcretion, or both, as responsible for the hyperuricemia. Evidence of overproduction of urate is provided by determination of the 24-hour urinary uric acid excretion. For adults ingesting a purine-free diet, a total excretion of up to 600 mg/day is considered within the normal range.¹⁴² For patients on regular diets, a value in excess of 1000 mg/day is clearly abnormal and an indication of overproduction, and values between 800 and 1000 mg/day are considered borderline. It has been suggested that overproduction of uric acid can be assessed simply by determining the ratio of uric acid to creatinine in the urine or the $C_{\text{urate}}/C_{\text{creatinine}}$ ratio. However, comparison of these two ratios with the 24-hour urinary uric acid excretion reveals a poor correlation in most patients.^{143,144} Exceptions include patients with specific enzymatic deficiencies or with rapid cell lysis during chemotherapy for leukemia or lymphoma.

Primary Gout

Renal mechanisms are responsible for the hyperuricemia in most cases of gout. Genetic factors exert an important control in the renal clearance of urate.¹⁴⁵ A careful comparison of uric acid clearances and excretion rates over a wide but comparable range of filtered loads of urate indicates that most gouty subjects have a lower ratio of urate-to-inulin clearance ($C_{\text{urate}}/C_{\text{inulin}}$ ratio) than do

Table 95-5 Classification of Hyperuricemia and Gout

Type	Metabolic Disturbance	Inheritance
Primary		
Molecular defects undefined		
Underexcretion (90% of primary gout)	Not established	Polygenic
Overproduction (10% of primary gout)	Not established	Polygenic
Associated with specific enzyme defects		
PRPP synthetase variants; increased activity	Overproduction of PRPP and uric acid	X-linked
HPRT deficiency, partial	Overproduction of uric acid; increased purine biosynthesis de novo driven by surplus PRPP; Kelley-Seegmiller syndrome	X-linked
Secondary		
<i>Associated with Increased Purine Biosynthesis De Novo</i>		
HPRT deficiency, "virtually complete"	Overproduction of uric acid; increased purine biosynthesis de novo driven by surplus PRPP; Lesch-Nyhan syndrome	X-linked
Glucose-6-phosphatase deficiency or absence	Overproduction plus underexcretion of uric acid; glycogen storage disease type I (von Gierke's disease)	Autosomal recessive
Fructose-1-phosphate aldolase deficiency	Overproduction plus underexcretion of uric acid	Autosomal recessive
<i>Associated with Increased ATP Degradation</i>		
Associated with increased nucleic acid turnover	Overproduction of uric acid	Most not familial
Associated with decreased renal excretion of uric acid	Decreased filtration of uric acid, inhibited tubular secretion of uric acid, or enhanced tubular reabsorption of uric acid	Some autosomal dominant; some not familial; most unknown
Idiopathic		Unknown

ATP, adenosine triphosphate; HPRT, hypoxanthine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate.

nongouty subjects.^{142,145,146} The excretion rates and the capacity of the excretory mechanism for uric acid are the same for gouty subjects and nongouty individuals (see Figure 94-8). The excretion curve, however, is shifted. Gouty subjects require serum urate values 2 or 3 mg/dL higher than those of controls to achieve equivalent uric acid excretion rates. Theoretically, the shift in the excretion curve in gouty subjects may result from reduced filtration of urate, enhanced reabsorption, or decreased secretion. Patients classified as exhibiting an overproduction of uric acid represent less than 10% of the gouty population.

Secondary Gout

Numerous secondary causes of hyperuricemia and gout can be attributed to a decrease in the renal excretion of uric acid. A reduction in the glomerular filtration rate leads to a decrease in the filtered load of urate and, consequently, to hyperuricemia. Patients with renal disease are hyperuricemic on this basis. Other factors such as decreased secretion of urate have been postulated in patients with some types of renal disease (e.g., polycystic kidney disease, lead nephropathy). Gout is a rare complication of the secondary hyperuricemia that results from renal insufficiency. When it occurs in this setting, there is likely to be a positive family history.

Diuretic therapy currently represents one of the most important causes of secondary hyperuricemia in humans. Diuretic-induced volume depletion leads to a decreased filtered load and enhanced tubular reabsorption of urate. A number of other drugs lead to hyperuricemia by a renal mechanism. These agents include low-dose aspirin, pyrazinamide, nicotinic acid, ethambutol, ethanol, and cyclosporine.

Decreased renal excretion of uric acid is thought to be an important mechanism for the hyperuricemia associated with several disease states. Volume depletion may be an important factor in patients with hyperuricemia associated with adrenal insufficiency or nephrogenic diabetes insipidus. An accumulation of organic acids leads to hyperuricemia. This is the case in starvation, alcoholic ketosis, diabetic ketoacidosis, maple syrup urine disease, and lactic acidosis of any cause (e.g., hypoxemia, respiratory insufficiency, chronic beryllium disease, acute alcohol intoxication). The renal basis of the hyperuricemia in conditions such as chronic lead intoxication, hypoparathyroidism, pseudohypoparathyroidism, and hypothyroidism remains unclear.

Secondary gout can also result from urate overproduction. Four specific defects cause urate overproduction as a consequence of accelerated de novo purine biosynthesis: hypoxanthine phosphoribosyltransferase (HPRT) deficiency, phosphoribosylpyrophosphate synthetase overactivity, glucose-6-phosphatase deficiency, and fructose-1-phosphate aldolase deficiency.

TREATMENT

KEY POINTS

Asymptomatic hyperuricemia is generally not treated, but its identification should lead to a search for the cause and/or associated conditions.

Episodes of acute gouty arthritis can be treated with colchicine, NSAIDs, adrenocorticotrophic hormone, and systemic or intra-articular steroids.

Prophylaxis against acute attacks with colchicine or NSAIDs can be effective but does not change the underlying process in the absence of concomitant urate-lowering therapy.

Starting urate-lowering therapy after a single attack of gout remains debatable, but recurrent attacks of gout, urate nephrolithiasis, tophaceous gout, and/or evidence of gout-induced joint damage are all accepted indications.

Xanthine oxidase inhibitors and uricosurics are effective at lowering serum urate levels in most patients.

Uricases such as pegloticase should be reserved for refractory tophaceous gout.

A serum urate of less than 6 mg/dL should be targeted.

Prophylaxis with colchicine, NSAIDs, or less preferably, systemic steroids should be continued for at least 6 months after initiation of urate-lowering therapy.

Long-term compliance with the treatment regimen remains a major issue in gout; forming a therapeutic alliance with the patient is critical.

Lifestyle modifications may help somewhat in the control of gout, especially reduced alcohol consumption, but are more important for the management of associated conditions such as obesity and hyperlipidemia.

4. To prevent or reverse associated features of the illness that are deleterious such as obesity, hypertriglyceridemia, and hypertension

Asymptomatic Hyperuricemia

The presence of hyperuricemia is rarely an indication for specific antihyperuricemic drug therapy. Rather, the finding of hyperuricemia should cause the following questions to be addressed:

1. What is the cause of the hyperuricemia?
2. Are associated findings present?
3. Has damage to tissues or organs occurred as a result?
4. What, if anything, should be done?

Hyperuricemia may be the initial clue to the presence of a previously unsuspected disorder. In 70% of hyperuricemic patients, an underlying cause can be readily defined by history and physical examination. The nature of the underlying cause may be useful in predicting the potential consequences, if any, of the elevated serum urate concentration. Therefore an underlying cause should be sought in every patient with hyperuricemia.

Whether to treat hyperuricemia uncomplicated by articular gout, urolithiasis, or nephropathy is an exercise in clinical judgment, and universal agreement is lacking. When considering whether to treat asymptomatic hyperuricemia with urate-lowering agents, the following data are pertinent:

- Although there are intriguing data from animal models to the contrary,¹⁴⁷ there is no good evidence that renal function is adversely affected by elevated serum urate concentrations.
- The renal disease that accompanies hyperuricemia is most often related to inadequately controlled hypertension.

The therapeutic aims in gout are as follows (Figure 95-8):

1. To terminate the acute attack as promptly and gently as possible
2. To prevent recurrences of acute gouty arthritis
3. To prevent or reverse complications of the disease resulting from the deposition of sodium urate or uric acid crystals in joints, kidneys, or other sites

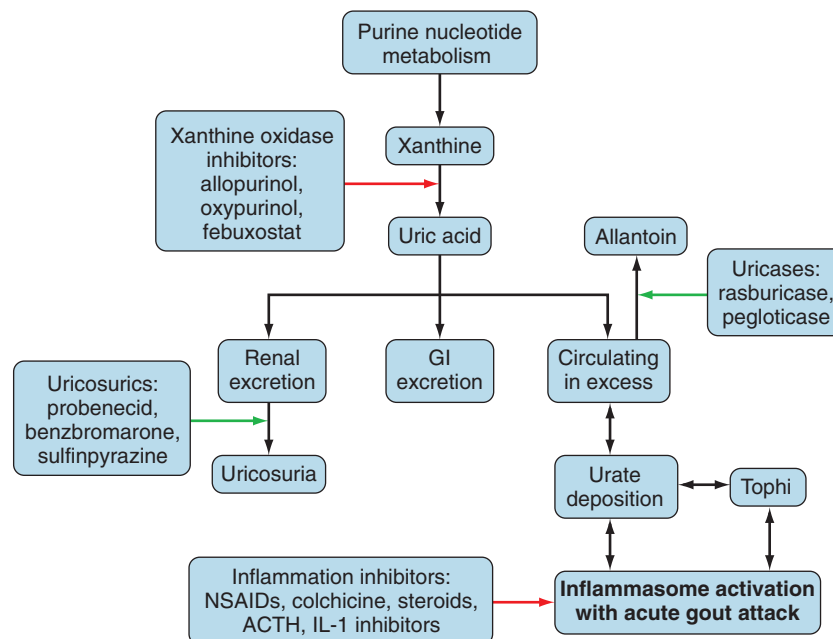

Figure 95-8 Treatment options for gout, including inhibitors of inflammation used for acute attacks and the available approaches for lowering serum urate when appropriate. Some inflammation inhibitors may also be used for prophylaxis when initiating urate lowering therapy. See text for details. Red arrows indicate inhibitory effects; green arrows indicate promoting effects. ACTH, adrenocorticotropic hormone; GI, gastrointestinal; IL-1, interleukin-1; NSAID, nonsteroidal anti-inflammatory drug.

- Although debate exists regarding whether hyperuricemia is an independent risk factor for coronary artery disease,⁹⁷⁻¹⁰⁰ there is no evidence that correction of hyperuricemia has an effect on the development of heart disease.

Thus it seems prudent not to treat hyperuricemia with specific antihyperuricemic agents until symptoms develop. Rare exceptions include individuals with a known hereditary cause of uric acid overproduction or patients at risk for acute uric acid nephropathy.

It is, however, strongly recommended that the cause of hyperuricemia be determined and any associated factors related to the process such as obesity, hyperlipidemia, alcoholism, and, especially, hypertension, be addressed. Fenofibrate and losartan might be appropriate agents for the treatment of hypertriglyceridemia and hypertension, respectively, in hyperuricemic individuals because each has modest uricosuric effects.^{148,149}

Acute Gouty Arthritis

The acute gouty attack may be successfully terminated by any of several drugs. For practical purposes, the choice in most situations is among colchicine, an NSAID, a corticosteroid preparation, or adrenocorticotrophic hormone (ACTH). In response to the recognition of the critical role IL-1 β plays in the initiation of gout attacks, trials of biologic inhibitors of IL-1 β for both the treatment and prophylaxis of acute gout have been undertaken with promising results.¹⁵⁰⁻¹⁵⁴ Although approved for the treatment of tumor necrosis factor (TNF) receptor-associated periodic fever syndromes, these expensive agents remain unapproved for gout at this writing. The timing of therapy initiation is more important than the choice of drug for acute gout.¹⁵⁵ With any of these agents, the sooner the drug is started, the more rapidly a complete response will be attained. Generally, colchicine is preferred for patients in whom the diagnosis of gout is not confirmed, whereas NSAIDs are preferred when the diagnosis is secure. If a patient cannot take medications by mouth or has active peptic ulcer disease, the choice is among intra-articular glucocorticoid, parenteral glucocorticoid, or ACTH. Local application of ice packs may help control the pain of an acute attack.¹⁵⁶ In some cases, analgesics including narcotics may be added as well. Drugs that affect serum urate concentrations including antihyperuricemic agents should not be changed (either started or stopped) during an acute attack. Just as sudden fluctuations in serum urate levels tend to precipitate an acute attack, an inflammatory reaction that is already in progress may be substantially worsened by a major change in the serum urate concentration.

Colchicine

Traditionally, the oral dosing schedule for colchicine was 0.5 or 0.6 mg taken hourly until one of three things occurred: joint symptoms eased; nausea, vomiting, or diarrhea developed; or the patient had taken a maximum of 10 doses. If 10 doses were taken without benefit, the clinician questioned the accuracy of the diagnosis. Many clinicians have

recommended that doses be taken every 2 to 6 hours to reduce side effects.¹⁵⁷ In 2009 the U.S. Food and Drug Administration (FDA) approved Colcris (URL Pharma, Inc.) as the first single-ingredient oral colchicine product for the treatment of acute gout flares and the prophylaxis of gout flares, as well as for familial Mediterranean fever in adults and children 4 years of age or older. The FDA ordered a halt to the marketing of unapproved single-ingredient colchicine preparations other than Colcris. The new recommendation for colchicine is the use of a low-dose regimen of 1.2 mg followed by 0.6 mg in 1 hour, for a total of 1.8 mg per attack. That protocol was based on the results of a randomized controlled trial of 184 patients with acute gout flares of less than 12 hours' duration that compared low-dose (74 patients) with high-dose colchicine (4.8 mg total over 6 hours; 52 patients) and with placebo (58 patients) with a primary endpoint of at least a 50% reduction in pain within 24 hours.¹⁵⁸ The low-dose approach resulted in comparable peak plasma concentrations and early gout flare control with much fewer side effects, particularly diarrhea and vomiting, compared with the high-dose approach. It should be noted that these were patients who started treatment within 12 hours of attack onset, and there was still a greater than 30% failure to achieve the primary endpoint in both treatment arms. The appropriate dosing of colchicine for attacks of greater duration remains unclear. The low-dose recommendations are in line with those of a EULAR panel of experts.¹⁵⁹ On the basis of two randomized trials, the recommended dosing for prophylaxis is 0.6 mg once or twice a day.^{160,161} Patients with severe renal insufficiency should be started at 0.3 mg a day. The marketing of unapproved, injectable colchicine was prohibited by the FDA in 2008 due to an unacceptable safety profile, with the potential for serious adverse events including death with intravenous administration.

Peak plasma concentrations of colchicine occur within 2 hours of oral administration. Although its plasma half-life is 4 hours, levels can be detected in neutrophils 10 days after ingestion. Colchicine has a low therapeutic index, with steady-state plasma concentrations after acute treatment ranging from 0.5 to 3 ng/mL and with toxic effects occurring at approximately 3 ng/mL.¹⁶² Therefore in most patients, the side effects precede or coincide with the improvement in joint symptoms. These side effects develop in 50% to 80% of patients using the old, high-dose regimen and include increased peristalsis, cramping abdominal pain, diarrhea, nausea, and vomiting. The drug must be stopped promptly at the first sign of gastrointestinal side effects.¹⁶³

Colchicine derives its effectiveness from its ability to interfere with acute inflammatory reactions in a variety of ways. Colchicine blocks the processing of IL-1 β ¹⁶⁴ and inhibits E-selectin-mediated adhesiveness to neutrophils.¹⁶⁵ Its action diminishes neutrophil L-selectin expression, random motility, chemotaxis, phospholipase A₂ activation, and IL-1 expression, as well as the stimulated elaboration of platelet-activating factor, crystal-induced chemotactic factor, and leukotriene B₄. Colchicine also inhibits endothelial cell ICAM-1 expression and mast cell histamine release and downregulates TNF receptors on macrophages and endothelial cells.

Nonsteroidal Anti-inflammatory Drugs

In a patient with an established diagnosis of uncomplicated gout, the preferred agent is an NSAID and indomethacin has been the traditional choice. Although this drug may be effective in doses as low as 25 mg four times a day, an initial dose of 50 to 75 mg, followed by 50 mg every 6 to 8 hours, with a maximum dose of 200 mg in the first 24 hours, has generally been recommended. To prevent relapse, it is reasonable to continue this dose for an additional 24 hours and then taper to 50 mg every 6 to 8 hours for the next 2 days. Clinical trials have shown that oral naproxen, fenoprofen, ibuprofen, sulindac, piroxicam, and ketoprofen, as well as intramuscular ketorolac, are also effective. In fact, all members of this family of drugs can be highly effective in the treatment of acute gouty arthritis including the cyclooxygenase-2 (COX-2) selective agents.¹⁶⁶

Corticosteroids

Intra-articular glucocorticoids are useful in the treatment of acute gout limited to a single joint or bursa.^{155,167} Oral, intramuscular, or intravenous glucocorticoids can also provide relief, but these agents are usually reserved for patients who are intolerant of colchicine or NSAIDs or who have medical conditions such as peptic ulcer disease or renal disease that contraindicate their use. Doses of glucocorticoids have been systematically studied, and generally, high doses (prednisone 20 to 60 mg/day) are necessary. Lower doses may not be effective, as evidenced by gout flares occurring in organ transplant patients who are taking maintenance prednisone at doses of 7.5 to 15 mg a day.¹⁶⁸ Anecdotally, rebound attacks were reported as steroids were withdrawn.

Adrenocorticotrophic Hormone

Single injections of intramuscular ACTH gel (25 to 80 IU) can terminate an acute gout attack.¹⁶⁹ More often, however, repeated administration is required every 24 to 72 hours. This treatment is effective postoperatively and may be more effective than glucocorticoids, possibly related to the mechanism of action. In addition to stimulating the adrenal cortex to produce corticosteroids, ACTH interferes with the acute inflammatory response through activation of melanocortin receptor-3.¹⁷⁰ Unfortunately, ACTH preparations, when available at all, have become prohibitively expensive.

Prophylaxis

The practice of giving small daily doses of colchicine as prophylaxis to prevent acute attacks is up to 85% effective.¹⁷¹ Colchicine 0.6 mg one to three times a day is generally well tolerated, although the drug may produce a reversible axonal neuromyopathy.¹⁷² This complication causes proximal muscle weakness with or without painful paresthesia and elevated serum levels of creatine phosphokinase. This is most often seen in patients with hypertension, renal dysfunction, or liver disease who are also using diuretics. Rhabdomyolysis may also occur in these

settings and is more common in individuals who are also taking a statin (HMG-CoA reductase inhibitor) or cyclosporine.¹⁷³

In patients who are unable to tolerate even one colchicine tablet per day, indomethacin or another NSAID has been used prophylactically at low doses (e.g., 25 mg indomethacin twice a day or naproxen 250 mg/day), with some success.¹⁷⁴ Maintenance doses of colchicine or an NSAID may make the difference between frequent incapacitation and uninterrupted daily activities. Prophylaxis is usually continued until the serum urate value has been maintained well within the normal range and there have been no acute attacks for 3 to 6 months. It is important to warn patients that colchicine discontinuation may be followed by an exacerbation of acute gouty arthritis and advise them what to do should an attack occur. Finally, prophylactic treatment is not recommended unless the clinician also uses urate-lowering agents. Prophylactic colchicine may block the acute inflammatory response but does not alter the deposition of crystals in tissues. When deposition continues without the warning signs of recurrent bouts of acute arthritis, tophi and destruction to cartilage and bone can occur without notice.

Control of Hyperuricemia

Elimination of hyperuricemia with antihyperuricemic agents can prevent and reverse urate deposition. Today, opinion differs as to when in the course of gout the clinician should start antihyperuricemic therapy. Some physicians regard the first gouty attack as a late event in a disorder marked by years of antecedent silent deposition of urate crystals in cartilage and other connective tissue. Others believe that because tophi and symptomatic chronic gouty arthritis develop in only a minority of cases and ordinarily develop slowly after many years of recurrent acute attacks, unnecessary or premature medication can be avoided without demonstrable penalty. In practice, it is rare to have a patient who never experiences a second attack.⁵⁹ The probability of such a benign course is greatest in patients who have only minimally elevated serum urate concentrations and normal 24-hour urinary uric acid values. Arguably, a case can be made for initiating antihyperuricemia therapy after the second attack in most patients.¹⁷⁵

Antihyperuricemic drugs provide a definitive method for controlling hyperuricemia. Although it is important to treat and prevent acute attacks of gouty arthritis with anti-inflammatory agents, it is the long-term control of hyperuricemia that ultimately modifies the manifestations of the gouty diathesis. Once started, treatment with specific urate-lowering agents is lifelong and the dose must be sufficient to maintain the serum urate level below 6.8 mg/dL, preferably between 5 and 6 mg/dL. Lowering the serum urate level from 11 mg/dL to 7.5 mg/dL may seem encouraging, but this change does not reverse the process. It merely slows the rate at which crystals continue to deposit. Generally, the lower the serum urate level achieved during antihyperuricemic therapy, the faster the reduction in tophaceous deposits.¹⁷⁶ The 5 to 6 mg/dL target is recommended because it is far enough below the saturation level of 6.8 mg/dL that it provides some margin for fluctuations in serum levels and

avoids excessive exposure to the medication, which might increase the chance of toxicity.

Reduction to target levels may be achieved pharmacologically by the use of xanthine oxidase inhibitors, uricosuric agents, or uricasers. Xanthine oxidase, the enzyme that catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid, is inhibited by allopurinol, oxypurinol, and febuxostat. Probenecid, sulfinpyrazone, and benz-bromarone are uricosuric agents that reduce serum urate concentrations by enhancing the renal excretion of uric acid. Rasburicase and pegloticase enzymatically convert urate to allantoin, which is much more soluble and readily excreted in the urine. These antihyperuricemic drugs do not have anti-inflammatory properties.

For those patients with gout who excrete less than 800 mg of uric acid per day and have normal renal function, reduction of the serum urate concentration can be achieved equally well with a xanthine oxidase inhibitor or a uricosuric drug. These agents are equally effective in preventing the deterioration of renal function in patients with primary gout.¹⁷⁷ In most cases, allopurinol is the drug of choice because it can be used with fewer restrictions compared with uricosuric agents.

In general, the ideal candidate for uricosuric agents is a gouty patient who is younger than 60 years and has normal renal function (creatinine clearance >80 mL/min), uric acid excretion of less than 800 mg per 24 hours on a general diet, and no history of renal calculi. Patients prescribed uricosuric agents should be counseled to avoid salicylate use at doses greater than 81 mg/day.¹⁷⁸

In certain situations, an inhibitor of xanthine oxidase is clearly the drug of choice in a gouty patient. Gouty individuals who excrete larger quantities of uric acid in their urine or who have a history of renal calculi of any type should be treated with a xanthine oxidase inhibitor (Table 95-6). The incidence of renal calculi is about 35% in patients with primary gout who excrete more than 700 mg/day of uric acid.¹²² There is also a greater risk for uric acid stones on initiation of uricosuric therapy. In addition, patients with tophi generally should receive a xanthine oxidase inhibitor to decrease the load of urate that must be handled by the kidney. Patients with gout and mild renal insufficiency can be given either type of agent, but probenecid and sulfinpyrazone would not be expected to work when the glomerular filtration rate is less than 50 mL/min. Allopurinol is effective in the presence of renal

Table 95-6 Indications for Xanthine Oxidase Inhibitor

Hyperuricemia Associated with Increased Uric Acid Production
Urinary uric acid excretion of 1000 mg or more in 24 hr
Hyperuricemia associated with HPRT deficiency or PRPP synthetase overactivity
Uric acid nephropathy
Nephrolithiasis
Prophylaxis before cytolytic therapy
Intolerance or Reduced Efficacy of Uricosuric Agents
Gout with renal insufficiency (GFR < 60 mL/min)
Allergy to uricosurics

GFR, glomerular filtration rate; HPRT, hypoxanthine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate.

Table 95-7 Maintenance Doses of Allopurinol Based on Creatinine Clearance Measurement*

Creatinine Clearance (mL/min)	Allopurinol Dose (mg)
0	100 every 3 days
10	100 every 2 days
20	100 daily
40	150 daily
60	200 daily
80	250 daily
100	300 daily
120	350 daily
140	400 daily

*These doses represent those that might be selected when initiating therapy with allopurinol. However, urate levels should be checked and the dosage adjusted so that the patient is taking the lowest dose that maintains the serum urate level below 5 to 6 mg/dL.

From Hande KR, Noone RM, Stone WJ: Severe allopurinol toxicity: description and guidelines for presentation in patients with renal insufficiency, *Am J Med* 76:47, 1984.

insufficiency, but doses may have to be decreased in that situation. Febuxostat needs no adjustment in mild to moderate renal insufficiency. A final indication for a xanthine oxidase inhibitor is the failure of uricosuric agents to produce a serum urate concentration lower than 6 mg/dL or patient intolerance of the uricosuric agent. A xanthine oxidase inhibitor and a uricosuric drug may be used in combination for a patient with tophaceous gout in whom it is not possible to reduce the serum urate below 6 mg/dL with a single agent. In most settings, if allopurinol does not cause the serum urate to drop below 6 mg/dL, it is the result of insufficient dosing or poor patient compliance.

Xanthine Oxidase Inhibitors

Allopurinol is a substrate for xanthine oxidase and is converted to oxypurinol by that enzyme activity. Oxypurinol is also an inhibitor of xanthine oxidase. Allopurinol is metabolized in the liver and has a half-life of 1 to 3 hours, but oxypurinol, which is excreted in the urine, has a half-life of 12 to 17 hours. Because of these pharmacokinetic properties, allopurinol is dosed on a daily basis and the dosage required to reduce serum urate levels is lower in patients with decreased glomerular filtration rates.

In 1984 guidelines for allopurinol dosing based on creatinine clearance were published (Table 95-7).¹⁷⁹ It is now apparent that these guidelines are useful for selecting the initial dosage of allopurinol, but they do not provide the effective maintenance dose for many individuals and following them does not protect against cutaneous hypersensitivity reactions.¹⁷⁹⁻¹⁸²

Allopurinol should be used at the lowest dose that lowers the serum urate level below 5 to 6 mg/dL. The most commonly prescribed dose is 300 mg/day, but this is insufficient to adequately reduce serum urate to the target level in 21% to 55% of individuals.^{44,183,184} Thus higher doses, with a maximum of 800 mg/day, may be required. The sudden lowering of serum urate concentrations that accompanies the initiation of allopurinol therapy may trigger acute gout attacks. This risk can be minimized by beginning prophylactic colchicine or an NSAID (see the previous discussion) 2 weeks before the first dose of allopurinol. Alternatively, the clinician can start allopurinol at a dose of 50 to 100 mg/

day and increase it by similar increments weekly until the desired target is reached.

About 20% of patients who take allopurinol report side effects, with 5% discontinuing the medication. Common side effects include gastrointestinal intolerance and skin rashes. The occurrence of a rash does not necessarily mean the drug should be discontinued. If the rash is not severe, the allopurinol can be withheld temporarily and resumed after the rash has cleared. Oxypurinol has been tried in patients who are sensitive to allopurinol, but its use is limited by poor gastrointestinal absorption and a high prevalence of cross-reactivity with allopurinol. Oral and intravenous protocols for desensitization to allopurinol have been successful in some patients following cutaneous reactions.^{174,185}

Other adverse reactions include fever, toxic epidermal necrolysis, alopecia, bone marrow suppression with leukopenia or thrombocytopenia, agranulocytosis, aplastic anemia, granulomatous hepatitis, jaundice, sarcoid-like reaction, and vasculitis. The most severe reaction is the allopurinol hypersensitivity syndrome, which may include fever, skin rash, eosinophilia, hepatitis, progressive renal insufficiency, and death.^{180,186} Autopsies reveal diffuse vasculitis involving multiple organs. This is most likely to develop in individuals with pre-existing renal dysfunction and in those taking diuretics.

Allopurinol is involved in relatively few drug-drug interactions. Its use potentiates the actions of other agents that are inactivated by xanthine oxidase. The most important of these are azathioprine and 6-mercaptopurine. In addition, allopurinol can reduce the activity of hepatic microsomal drug-metabolizing enzymes and prolong the half-lives of warfarin and theophylline. Rash may be more common in patients using allopurinol and ampicillin, and bone marrow suppression may be increased in those also taking cyclophosphamide.

Febuxostat (Uloric, Takeda Pharmaceuticals America, Inc.) was recently approved for use in the treatment of gout on the basis of one phase II, three phase III, and two open-label extension trials.^{44,150,187-191} Febuxostat is a potent xanthine oxidase inhibitor that differs from allopurinol in that it is of another chemical class and is a selective inhibitor of enzyme activity. These properties indicate that it would be an excellent alternative for individuals who are intolerant of or hypersensitive to allopurinol. In fact, febuxostat appeared to outperform allopurinol in achieving target serum urates in the clinical trials. Importantly, though, allopurinol doses were fixed and clearly too low in these trials, and therefore it is impossible to make firm conclusions about the comparative efficacy of these two agents. In the United States, febuxostat doses of 40 or 80 mg a day have been approved, whereas in Europe, doses of 80 and 120 mg a day are recommended. The dosage of febuxostat does not need to be adjusted in individuals with mild to moderate renal insufficiency. The same precautions apply as with allopurinol in terms of use with other agents metabolized by xanthine oxidase including azathioprine and 6-mercaptopurine. Diarrhea, dizziness, headache, liver function test abnormalities, and altered thyroid function tests were the most common side effects noted in the clinical trials. Cardiovascular events were numerically higher with febuxostat than with other treatments, but when total

drug exposures were taken into account, the incidence was the same.¹⁹² In Europe, the use of febuxostat in patients with ischemic heart disease or congestive heart failure is not recommended. After the FDA-required CONFIRMS trial¹⁸⁹ did not detect increased cardiovascular risk with febuxostat, the FDA approved dosing of 40 mg and 80 mg daily in the United States. Takeda, under guidance from the FDA, has committed to cardiovascular postmarketing. Gout flares were higher early on with febuxostat compared with allopurinol, emphasizing again the need for prophylaxis of up to 6 months when initiating urate-lowering therapy.

Febuxostat and allopurinol have similar safety profiles. Patients with hypersensitivity reactions to allopurinol who were given febuxostat were able to tolerate the new drug.¹⁹³ Febuxostat should be considered mainly for patients intolerant to allopurinol, for those whose gout is not controlled with other urate-lowering treatments, and for those with renal insufficiency (creatinine clearance >30 mL/min). Febuxostat should be tried before an attempt at allopurinol desensitization. Finally, febuxostat should be used before uricosuric drugs in patients with nephrolithiasis.

Uricosuric Agents

Administration of a uricosuric agent increases the rate of renal uric acid excretion.¹⁹⁴ In the kidney, there are separate transport systems for the secretion and reabsorption of organic ions including uric acid. Because urate is reabsorbed by a renal tubular brush border anion transporter, the reabsorption of urate can be inhibited when uricosuric agents are present in the lumen and compete with urate for the transporter. This inhibition of reabsorptive anion transporter requires high doses of uricosuric agents. Because the secretory transport system is quantitatively much smaller than that for reabsorption and is located in the basolateral membrane of the tubule, when uricosuric agents are taken in low doses, they actually decrease the renal excretion of uric acid and raise serum urate levels by inhibiting the secretory transport system.

Probenecid and sulfinpyrazone are the most widely used uricosuric agents available in the United States. Benzbromarone is used for this purpose in other countries as well. However, many other agents can reduce serum urate levels by enhancing the renal excretion of uric acid (see Table 95-8).

Probenecid is readily absorbed from the gastrointestinal tract. Its half-life in plasma is dose dependent, varying from

Table 95-8 Drugs That Are Uricosuric in Humans

Acetohexamide	Glycerol guaiacolate
Amflutizole	Glycine
Ascorbic acid	Glycopyrrolate
Azapropazone	Iodopyracet
Azauridine	Iopanoic acid
Benzbromarone	Losartan
Calcitonin	Meclofenamic acid
Calcium ipodate	Orotic acid
Citrate	Outdated tetracyclines
Dicumarol	Phenolsulfonphthalein
Diflunisal	Probenecid
Estrogens	Salicylates
Fenofibrate	Sulfinpyrazone

6 to 12 hours. This can be prolonged by the concomitant use of allopurinol. Probenecid is metabolized in vivo, with less than 5% of the administered dose recovered in the urine. The maintenance dosage of probenecid ranges from 500 mg to 3 g per day and is administered two or three times a day. Acute gouty attacks may accompany the initiation of this medication, and, as with all uricosuric agents, patients using probenecid are at increased risk for developing renal calculi. With long-term use, up to 18% of individuals develop gastrointestinal complaints and 5% develop hypersensitivity and rash. Although serious toxicity is rare, approximately one-third of individuals eventually become intolerant of probenecid and discontinue its use. Probenecid alters the metabolism of several other agents by several mechanisms (Table 95-9). Concomitant use of probenecid can increase the potency of some agents by decreasing their renal excretion, delaying their metabolism, or impairing their hepatic uptake. It may decrease the effectiveness of other medications by reducing their volume of distribution.

Sulfinpyrazone is completely absorbed from the gastrointestinal tract and has a half-life of 1 to 3 hours. Most of the drug is excreted in the urine as the parahydroxyl metabolite, which is also uricosuric. Sulfinpyrazone is usually given at a dosage of 300 to 400 mg/day divided into three or four doses. The rates of tolerability and types of adverse reactions are similar to those with probenecid. Unfortunately, sulfinpyrazone is no longer readily available.

Benzbromarone is more potent than probenecid and sulfinpyrazone.¹⁷⁷ It is well tolerated and effective in cyclosporine-treated renal transplant patients. It can be used in those with moderate renal dysfunction (creatinine clearance approximately 25 mL/min).
